$$Z_x = \frac{X_p^2 R_p + JR_p^2 X_p}{R_p^2 + X_p^2}$$

$$Z_x = R_s \pm JX_s$$

Figure 2. Series connection for impedance measurements

Point A also grounded

3. High Q-coil and low power-factor calibrated capacitor.

4. Vacuum-tube voltmeter.

As in the case in any measurement procedure, lead lengths and proximities should be watched very carefully.

Description

Figure 1 indicates a method which is basically a substitution method (similar to the parallel connection method with the Q-meter) for measuring an unknown impedance consisting of resistance and inductive reactance or capacitive reactance. By using a substitution method, many unknown factors cancel out, such as Q of coils, wave form of source, and so forth. The only requirement is an accurate calibration or measurement of the values of C and R. The latter should be noninductive and have little distributed capacity.

The purpose of R_L is to provide a firm source of r-f voltage of E_a which will not vary too much with changing impedances. This may not be too essential. The series resistance R_1 is to provide an output of constant-current character in order to detect resonance of the circuits by watching E_b. L could be a tuning unit coil normally used to resonate coupling capacitors. C could be a mica decade capacitor box from 0.0001 to about 0.1 microfarad.

Method of Measurement Parallel Connection Method (Figure 1)

1. Load the transmitter or generator into R_L so that about maximum E_a is obtained and it is of good wave form at the frequency desired.

2. Connect the rest of the circuit with S_1 open, and resonate the circuit by adjusting L and C for a maximum value of E_b. R_1 should be kept reasonably large so that a fairly sharp indication of resonance is obtained. Either L or C must be greater than the equivalent of L or C of X_p in the unknown impedance. Note the value of E_b and C.

3. Close switch S_1, and resonate by varying C. If C has to be diminished, then X_p is of capacitive reactance and vice versa for inductive reactance. Also, if resonance cannot be obtained with zero capacity at C, then step 2 will have to be repeated with a larger value of C and a lower value of L. When step 3 is complete, note new value of E_b and C. If E_a varies, this information must also be kept. The equations given after Figure 1 and in the following will indicate the method of calculating the elements of the unknown impedance.

E_{a1}, E_{b1}, C_1, and Q_1 = readings with $S1$ open.
E_{a2}, E_{b2}, C_2, and Q_2 = readings with $S1$ closed
C_1 and C_2 are read from C. Q_1 and Q_2 are calculated.

$$Q_1 = \frac{E_{b1}}{E_{a1}\ E_{b1}} \times \frac{R_1 C_1 f}{1.59 \times 10^8}$$

$$Q_2 = \frac{E_{b2}}{E_{a2}\ E_{b2}} \times \frac{R_1 C_2 f}{1.59 \times 10^8}$$

$$Q_x = \frac{Q_1 Q_2}{Q_1 - Q_2}$$

Where Q_x is the unknown impedance

$$C_p = C_1 - C_2$$

If $(C_1 - C_2)$ is negative, then X_p is inductive and

$$L_p = \frac{2.53 \times 10^{10}}{f^2 (C_2 - C_1)}$$

$$X_p = \omega L_p = \frac{1}{\omega C_p} = \frac{1.59 \times 10^8}{f(C_2 - C_1)}$$

$$R_p = \frac{Q_x}{\omega L_p} = Q_x C_p \omega = \frac{1.59 \times 10^8 Q_1 Q_2}{f C_1 (Q_1 - Q_2)}$$

Series Connection Method (Figure 2)

This method should be particularly useful where impedances are of very low values and not particularly suited to the method described for the parallel connection. It consists of using the same elements by putting the unknown impedance in series with the resonant circuit instead of in parallel with it. It is expected that this method will not be used as much as the one above. Figure 2 indicates the connection of the apparatus and step 1 is identical with step 1 in the previous case. R_0 could be a noninductive resistor of some convenient size so that, for the series resonant case, E_b does not become too low for accurate measurement.

After the transmitter is loaded into R_L, close $S2$, open $S1$, connect the whole circuit to R_L and resonate L and C. The use of R_0 complicates the calculation somewhat, but it may be necessary in order to keep E_b from being so small that inaccuracies arise from stray pickup in the voltmeter leads. If the measurements can be made with R_0 short-circuited, it would be desirable. At resonance, note values of E_a, E_b, and C.

Open $S2$, close $S1$, resonate the circuit by watching for a minimum E_b and note new values of E_a, E_b, and C. The following equations will indicate the method of calculating the unknown impedance.

$$Q_1 = \frac{1.59 \times 10^8}{C_1 R_1 f} \times \frac{E_{a1} - E_{b1}}{E_{b1}}$$

$$Q_2 = \frac{1.59 \times 10^8}{C_2 R_1 f} \times \frac{E_{a2} - E_{b2}}{E_{b2}}$$

$$Q_x = \frac{(C_1 - C_2) Q_1 Q_2}{C_1 Q_1 - C_2 Q_2}$$

Where Q_x is the unknown impedance

$$C_s = \frac{C_1 C_2}{C_2 - C_1}$$

If $C_2 - C_1$ is negative, then X_s is inductive and

$$L_s = \frac{2.53 \times 10^{10} (C_1 - C_2)}{f^2 C_1 C_2}$$

$$R_s = \frac{\omega L_s}{Q_x} = \frac{1}{\omega Q_x C_s} = \frac{1.59 \times 10^8 \left(\frac{C_1}{C_2} Q_1 - Q_2 \right)}{f C_1 Q_1 Q_2}$$

$$X_s = \omega L_x = \frac{1}{\omega C_x} = \frac{1.59 \times 10^8 (C_1 - C_2)}{f C_1 C_2}$$

Conclusions

The parallel method of measurement gives the impedance as effective parallel elements and the equivalent series elements will have to be calculated. For the parallel case:

$$Z_s = \frac{X_p^2 R_p + J R_p^2 X_p}{R_p^2 + X_p^2}$$

Therefore:

$$R_s = \frac{X_p^2 R_p}{R_p^2 + X_p^2}$$

Figure 3. Circuit for measuring line trap impedances

Figure 4. Circuit for measuring insertion losses

$$X_s = \frac{R_p^2 X_p}{R_p^2 + X_p^2}$$

To be comparable with series connection measurements where

$$Z_s = R_s + JX_s$$

If the results give Q_s a value greater than ten, then

$$X_s = X_p$$
$$L_s = L_p$$
$$C_s = C_p$$
$$R_p = Q^2 R_s$$

The units to be used for formulas in these two methods are:

R = resistance in ohms
X = reactance in ohms
L = inductance in microhenries
C = capacitance in micromicrofarads
f = frequency in kilocycles per second

The following is a suggested set of data to obtain: f; E_{a1}; E_{b1}; C_1; E_{a2}; E_{b2}; C_2; $(C_1 - C_2)$; and Q_s.

The rest of the values of the unknown impedance can be calculated as desired.

Both methods described above assume the capacitor C has zero power factor or infinite Q. Actually, the results will be quite accurate if C is made up of good mica capacitors which have Q's of 1,000 to 10,000.

Part II. Method of Measuring Impedance of Line Traps

1. The impedance of a single-frequency trap can be obtained best by calculation when f, L, and Q are known. If Q is not known, then it can be determined by a single-frequency measurement with the method described subsequently.

2. The impedance of 2-frequency traps can be found easier by measurement as follows (single-frequency traps can be measured this way also). (Note Figure 3).

$$Z = \frac{E_a}{E_b} R$$

Use vacuum tube voltmeter for E_a and E_b.

The foregoing formula is accurate enough if E_a/E_b is large enough, particularly for off-resonance conditions of line trap. By adjusting R, keep E_a equal to $10E_b$ if at all possible.

The reason for L, C, and R_L is to insure as nearly a pure sine wave of the signal as possible across R_L. Therefore, L/C should be high.

This gives the total impedance and does not evaluate the resistance and reactance components.

Part III. Method of Measuring Transmission or Insertion Losses

It is often desirable to know the insertion loss of a given device when connected into a circuit or transmission line. These transmission losses may be observed over a narrow band of frequencies or over a broad band of frequencies, as in the case of certain transformers and transmission lines or cables. This method is useful and accurate when the insertion loss is in excess of ten decibels. It is particularly useful in determining the attenuation of transmission lines which are relatively long and determining effects of other lines on this attenuation. The same method can be used to determine the transmission characteristics of tuning units and 2-frequency carrier telephone channels.

In the diagram shown in Figure 4, R_s should be equal to the input impedance of the unknown device, and R_L should be equal to the output impedance of the unknown device. R_s is determined by adjusting E_a for half the value of E_a. R_L is normally adjusted for maximum power into this resistance and will give the proper match at the other end. R_s and R_L should be adjusted for some normal operating point and left fixed over the frequency range to be studied.

Readings should be taken of E_a and E_b, and a curve should be plotted which gives the decibel differential between the two voltages. In addition, six decibels should be subtracted from this differential to take into account the voltage loss in R_s when there is no insertion loss.

The use of R_s gives a method which approximates measuring input and output power.

Part IV. Method of Determining the Characteristics of Transmission Lines and Cables by Means of Open and Short-Circuit Measurements

Where transmission lines or cables are relatively short and the loss is less than ten decibels, the transmission measurement described in Part III becomes a little inaccurate. The type of measurement described here involves more calculation, but greater accuracy can be obtained on values of attenuation.

By means of a method of measuring impedance described in Part I, the open- and short-circuit measurements can be made from which calculations will give characteristic impedances, loss per unit length, and speed of propagation.

From the method in Part I the value obtained for open-circuit impedance is:

$$Z_{oc} = R_o - JX_o$$

The value for short-circuit impedance is

Figure 5. Circuit for measuring noise and interference

$Z_{sc} = R_s + JX_s$

Solve for A and B from

$$A = \frac{R_oR_s + X_oX_s}{R_o^2 + X_o^2}$$

$$B = \frac{R_sX_o + R_oX_s}{R_o^2 + X_o^2}$$

Then

$$\tanh 2\alpha l = \frac{2A}{1 + A^2 + B^2}$$

$$\tanh 2\beta l = \frac{2B}{1 - (A^2 + B^2)}$$

By evaluating to determine α, the attenuation per unit length of line can be determined.

The preceding equations come from the following relations:

$$\tanh \gamma l = \tanh (\alpha + j\beta) = \frac{Z_{sh}}{Z_{oc}} = A + JB$$

Also

$$Z = \sqrt{Z_{sc}Z_{oc}} = \text{characteristic impedance.}$$

Part V. Method of Measuring Noise and Interference

In order to measure radio-frequency noise and interference in the carrier band of frequencies, it is necessary to have some kind of electronic voltmeter which will read the voltage. Field-strength instruments are available for measuring these quantities, but in general they do not cover this particular frequency range. In order to use them, it is necessary to build a converter to convert the frequency range up to the range for which the field-strength meter is designed. Wherever possible, a field-strength meter should be used for measuring noise and interference.

In view of the fact that field-strength meters are likely not to be too plentiful in the field, it is possible to get reasonably reliable data by means of the substitution method using a carrier-current receiver. This receiver should be a receiver designed for reception of voice-modulated signals so that it has a band width of approximately 6 kc, and fairly good selectivity. The receiver should employ four or more tuned circuits in order that the selectivity will be reasonably good.

With the receiver connected through a coupling capacitor to the line as shown in Figure 5, noise or interference will produce a detector voltage or current which can be noted. Then the receiver is switched to a calibrated signal generator, and the same reading on the detector meter is obtained by adjusting the output of the signal generator. The output of the signal generator is then equal to the voltage received from the line. If a calibrated signal generator is not available, a suitable generator (transmitter) and attenuator together with a vacuum-tube voltmeter can be used.

When measuring interference, which is a single radio frequency, in this manner the selectivity of the receiver and time constants of the detector circuit do not affect the accuracy of measurement. However, when random noise is measured, these two characteristics will influence the data obtained. Therefore, when taking data on random noise, information on selectivity such as a complete curve or a figure on the frequency where the response is 3 decibels down together with the number of tuned circuits should be made part of the data. Also, the complete information on the detector circuit as to the type of detector and time constants should be included.

The receiver should be operated near the coupling capacitor so that no transformer or cable is in between, which would bring inaccuracies with regard to impedance levels and so forth.

The receiver should be of high input impedance or decoupled (to prevent loading) from the power line by a 5,000-ohm resistor.

In this way, the data will more nearly represent the noise voltage on the power line itself and give a better base for comparing data from different locations. The coupling capacitor should be resonated by a tuning coil at the frequency for which the receiver is tuned.

Discussion

A. A. Sackler (Ebasco Services Incorporated, New York, N. Y.): With the co-operation on the part of the men in the field, the recommendations embodied in this report by the carrier current committee should make enough carrier current data available to take much of the guess work out of the installation of carrier current channels.

Now that the methods of making carrier current tests on transformers, capacitor potential devices, instrument transformers, and so forth have been standardized the next logical step would seem to be to have these measurements made on the equipment at the time of their manufacture. This would provide much more accurate data than could be obtained from field measurements, for at their best field measurements are usually made with make-shift equipment and under adverse conditions which result in low accuracy.

Naturally, measurement of transmission lines, cables, and busses must be made in the field. In this connection it may be of help if measuring procedures were outlined in more detail to allow for better comparison of data. An example of this would be definite information as to whether unused phases should be grounded or left floating when making measurements or whether it is advisable to make measurements for both these conditions.

The authors have also stated that no suitable r-f bridges are available at present for making measurements. We have had some experience in using a simple homemade r-f bridge in making characteristic impedance measurements on a 132-kv cable. The methods described in parts III and IV of the paper were also used. While some discrepancies existed in the results obtained by the three methods, it is quite possible that the bridge method was as accurate as the two methods described by the committee. It would seem worthwhile to further investigate the possibility of using r-f bridges for making measurements.

In part III, describing the method of measuring transmission and insertion losses, it should be noted that this method is also useful for measuring the characteristic impedance of lines as well as measuring losses. The magnitude of the impedance is obtained without the necessity of making any calculations.

In part III of their paper, the authors also recommend that the values of R_s and R_l be left fixed over the frequency range to be studied. However, in many cases the impedance of the devices may vary appreciably with frequency, in which case inaccuracy will result due to the impedance mismatch. In these cases it may, therefore, be necessary to readjust R_s and R_l at several points in the frequency spectrum under consideration.

Simplified Calculation of Fault Currents

AN AIEE COMMITTEE REPORT

Synopsis: A simplified procedure for the calculation of short-circuit currents was presented in earlier reports[1,2] which has been found to be generally satisfactory. It is intended for general use by the industry as a simplified method of approximating the magnitude of fault currents; however, other more rigorous methods should be used where required.

THE PRECISE determination of short circuit currents involves a complicated calculation which in many instances is not necessary. Certain approximations can be made although a degree of judgment must be applied in any simplified method. The method presented here is based upon the determination of an initial value of rms symmetrical current with which multiplying factors are used for application purposes. It may be used, where applicable, in place of the methods which involve the use of decrement curves. It is believed that this procedure is sufficiently accurate to serve as a reliable basis for the usual application of interrupting devices and as a preliminary basis for relay settings. A recent review of the procedure revealed the need for certain modifications in order to improve and bring the previous report up to date.

The multiplying factors given in Tables I and II take account of generator decrement and the asymmetrical value of current as influenced by the system d-c time constant, and they are adjusted to make allowance for the increase in generator excitation required to maintain normal terminal voltage under load conditions. They neglect, however, such influences as generator voltage regulators and phase-angle differences between generator rotors, which have but little effect within the usual operating time of modern circuit breakers.

A comparison of the current magnitudes determined by these factors with those determined from decrement curves[4] previously in general use is given in Figure 1. The time intervals selected for comparison correspond to power circuit breaker interrupting time ratings of 2, 3, 5 and 8 cycles, with time from inception of fault to parting of contacts assumed to be not less than 1, 2, 3, and 4 cycles respectively. The fault current and reactances are based on the system kilovolt-amperes. The earlier "decrement curves" gave rms total current, but for purposes of comparison, Figure 1 also includes "a-c component only." The total rms current (decrement curve method) is based on the assumption that for all short circuits the decay of the d-c component of current has a time constant of 0.15 second. However, as this 0.15 second time constant is larger than the values usually encountered in any equipment except generators and reactors, results are often conservative. In the general case, actual total rms currents are no greater than the "simplified method" values indicated in Figure 1. The d-c time constant may be expressed generally as equal to $(1/2\pi f)(X/R)$ in seconds, or $(1/2\pi)(X/R)$ in cycles, where X is the reactance in ohms at system frequency f and R the d-c resistance to the point of fault.

In this method of determining fault currents, symbols are used with the significance given in the following:

E = phase to neutral voltage
X_1 = direct-axis positive-sequence reactance, either transient or subtransient as specified, in ohms per phase
X_2 = negative-sequence reactance, ohms per phase
X_0 = zero-sequence reactance, ohms per phase
R_0 = zero-sequence resistance, ohms per phase

The type of fault (number of phases involved, with or without ground) which will result in the maximum fault current varies with the relative values of the different circuit constants.

The 3-phase short-circuit current is E/X_1. The line-to-line short-circuit current is $\sqrt{3}E/(X_1+X_2)$. Since X_2 is usually equal to X_1, this current seldom exceeds 86 per cent of the 3-phase short-circuit current, and, consequently, for line-to-line faults the 3-phase fault-current value is generally satisfactory.

The line-to-ground short-circuit current is $3E/(X_1+X_2+X_0)$. Since X_2 is usually approximately equal to X_1 (using the subtransient value for X_1), this expression often is shortened to $3E/(2X_1+X_0)$. In practical cases, regardless of the value X_2, this last expression is satisfactory for determining the conductor current in either single or double line-to-ground fault.

Procedure

The following gives a resumé of the procedure and the various multiplying factors to be used with currents calculated by the formulas just stated. Tables I and II show what reactance quantity should be used for representing the machines in the positive-sequence network.

Interrupting Duty. Determine "highest value of rms symmetrical current for any type of fault" by E/X_1 or $3E/(2X_1+X_0)$, whichever is greater, except that with resistance grounded systems when R_1 is greater than $2.23X_1$, no consideration need be given to the latter expression $3E/(2X_1+X_0)$. Use multiplying factors as given in Table I for specific type of apparatus. It has been

Paper 48-258, recommended by the AIEE switchgear committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted August 2, 1948; made available for printing August 20, 1948.

The original report sponsored in 1942 by the AIEE committee on protective devices was prepared by a working group consisting of W. F. Skeats, W. M. Hanna, H. A. Travers, C. F. Wagner, and C. A. Woodrow. It was revised in 1943 by protective devices committee.

This revision of the report was prepared during 1947–48 by a working group of the AIEE switchgear committee—J. R. North, *Chairman;* O. Bauhan, R. M. Ferrill, S. B. Griscom, W. M. Hanna, R. T. Henry, H. A. Travers, C. A. Woodrow, and D. G. Worth.

Table I. Multiplying Factors for Application of Interrupting Devices

	Multiplying Factor	Reactance Quantity For Use in X_1: Synchronous Generators and Condensers	Synchronous Motors	Induction Machines
A. Circuit Breaker Interrupting Duty				
1. General case				
8-cycle or slower circuit breakers*	1.0	subtransient**	transient	neglect
5-cycle circuit breaker	1.1			
3-cycle circuit breaker	1.2			
2-cycle circuit breaker	1.4			
2. Special case for circuit breakers at generator voltage only. For short-circuit calculations of more than 500,000 kva (before the application of any multiplying factor) fed predominantly direct from generators, or through current-limiting reactors only.				
8-cycle or slower circuit breakers*	1.1	subtransient**	transient	neglect
5-cycle circuit breakers	1.2			
3-cycle circuit breakers	1.3			
2-cycle circuit breakers	1.5			
3. Air circuit breakers rated 600 volts and less	1.25	subtransient	subtransient	subtransient
B. Mechanical Stresses and Momentary Duty of Circuit Breakers				
1. General case	1.6	subtransient	subtransient	subtransient
2. At 5,000 volts and below, unless current is fed predominantly by directly connected synchronous machines or through reactors	1.5			
C. Protector Tubes				
1. Maximum rating	1.0	subtransient	subtransient	subtransient
2. Minimum rating—use minimum system capacity and minimum of E/X_1 or $3E/(2X_1+X_0)$	1.0			
D. Fuses				
1. At 15,000 volts, or below, except for current-limiting fuses when the fuse is located remote from generating stations or primary substations (that is, X/R is less than 4)	1.2	subtransient	subtransient	subtransient
2. All other cases, including all current-limiting fuses regardless of voltage	1.6			

*Since old circuit breakers are slower than modern ones, it might be expected a low multiplier could be used with old circuit breakers. However, modern circuit breakers are likely to be more effective than their slower predecessors, and, therefore, the application procedure with the older circuit breakers should be more conservative than with modern circuit breakers. Also, there is no assurance that a short circuit will not change its character and initiate a higher current flow through a circuit breaker while it is opening. Consequently, the factors to be used with older and slower circuit breakers may well be the same as for modern 8-cycle circuit breakers.

**This is based on the condition that any hydroelectric generators involved have amortisseur windings. For hydroelectric generators without amortisseur windings, a value of 75 per cent of the transient reactance should be used for this calculation rather than the subtransient value.

Table II. Multiplying Factors for Preliminary Relay Settings

	Multiplying Factor	Reactance Quantity For Use in X_1: Synchronous Generators and Condensers	Synchronous Motors	Induction Machines
1. High-speed current actuated	1.0	subtransient	subtransient	subtransient
2. Time overcurrent	1.0	transient	transient	neglect

found that for systems where the 3-phase fault kilovolt-ampere at the generator bus voltage does not exceed 500,000 (before the application of multiplying factors), no additional multiplying factor is required. When calculated values exceed 500,000 kva these multiplying factors should be increased as indicated in Table I, section A2, to compensate for the longer d-c time constant of large generators and reactors.

For the application of protector tubes,[3] both minimum and maximum fault currents must be determined. The minimum fault current should be determined on the basis of minimum connected synchronous capacity and symmetrical current using E/X_1 or $3E/(2X_1+X_0)$, whichever gives the lower value. Special consideration is required where ground resistance appreciably can reduce this line-to-ground fault current. Protector tubes are rated in terms of symmetrical current but are designed to withstand full asymmetrical current and therefore the multiplying factor is 1.0.

Fuses are rated on total current, and, as the time durations involved are very short, their required interrupting capacity should be based on the total rms current at one-half cycle, using subtransient reactances for both synchronous and induction machines. Two cases should be considered.

1. At 15,000 volts or below, except for current-limiting fuses, when the fuse is located remote from generating stations or primary substations (that is, X/R is less than 4) multiply by 1.2. This is because the rms current of a maximum displaced wave in the first half cycle will not exceed 1.2 times the calculated symmetrical current.

2. In all other cases, including current-limiting fuses, regardless of voltage, multiply by 1.6.

In determining the X/R ratio in the calculation, the entire X value from source of power to the fuse location should be used but the R value only from the fuse back to the first primary substation. The error in neglecting the remainder of R is negligible, and the difficulty in obtaining rigorous values is not commensurate with the increase in accuracy obtained. If the X/R ratio is less than 4, the lower multiplying factor of 1.2 is permissible; otherwise the factor of 1.6 should be used. Although it is recognized that the same line of reasoning could be applied to higher-voltage fuses which are not current limiting, a survey of many cases indicated that the majority of these cases would fall in the 1.6 multiplier class.

For all current-limiting fuses, the multiplying factor will be 1.6. This is because the rating of such fuses is based on an unsymmetrical current value equal to 1.6 times the symmetrical current.

Mechanical and Momentary Duty. For many purposes, it is necessary to know the maximum possible rms current (including both a-c and d-c components) which can flow in the circuit. Allowing for over-excitation of generators on account of load, the rms value of current as calculated for zero time is about 1.8 times the value calculated by dividing phase to neutral voltage by subtransient reactance. As there will always be some delay even in the first half cycle; however, a multiplier of 1.6 is acceptable.

In some instances, as when transmission line or cable reactance is an important factor in the limitation of current, the factor 1.6 may be higher than necessary. In such applications at 5,000 volts and below, the ratio of reactance to resistance is sufficiently low so that the d-c component decreases very greatly during the first half cycle. Thus within this voltage range, and except where the bulk of the power is supplied by generators at the point of fault, a factor of 1.5 may be used instead of 1.6.

Low-Voltage Systems. Low-voltage air circuit breakers (rated 600 volts or less) are often instantaneous in operation and part contacts during the first half cycle. These circuit breakers, however, are rated on the basis of average current in

Figure 1A

——— Decrement curve method
——— Simplified method

Figure 1B

——— Decrement curve method
——— Simplified curve

the three phases, and circuits on which they are installed rarely have X/R ratios exceeding 12. This corresponds to an average rms current at one-half cycle after instant of fault which equals 1.25 times the symmetrical current. Such circuit breakers therefore may be applied on the basis of 1.25 times the 3-phase initial symmetrical current using subtransient reactance and including both synchronous and induction motors.

In calculating the equivalent system impedances, it should be remembered that at low voltages even small impedance values become of importance, and all elements of the circuit, including current transformers, disconnects, switches, bus runs, and their connections should be taken into consideration.

Overcurrent Protective Relays. In approximating the settings of overcurrent relays, the fault currents for two conditions should be determined:

1. The maximum initial symmetrical current for maximum connected synchronous capacity as determined by E/X_1 or $3E/(2X_1+X_0)$, whichever is greater, except that, when R_0 is greater than $2.23X_1$, no consideration need be given to the expression $3E/(2X_1+X_0)$.

2. The minimum symmetrical current for minimum connected synchronous capacity as determined by $0.866E/X_1$, or $3E/(2X_1+X_0)$ for reactance grounded systems. In particular situations, allowance should be made for remote fault locations and fault resistance.

Ground, distance, balanced, and other types of relays require special consideration.

Insulators to Withstand Air-Borne Deposits

J. J. TAYLOR
ASSOCIATE AIEE

Synopsis: Representative types of fog insulators are classified according to design principles. The general conclusion is that each type has inherent limitations and that a completely satisfactory solution of the problem is still to be found.

The mechanism of leakage surge flashover is examined. Continued research into methods of establishing a voltage gradient by resistance means is recommended. In such research, leakage surge counters promise to be a useful tool. A description is given of surge measuring equipment and of results obtained on the group of outdoor tests.

HIGH-VOLTAGE insulators are designed to serve as mechanical supports and electrical barriers. That they may fail in their electrical function because of excessive surface dirt and moisture was recognized at least 70 years ago. In 1878 Johnson and Philips patented the oil-filled insulator shown in Figure 1, Group 1(A). A few years later Alf Sinding-Larsen of Norway invented an insulator with heating elements to maintain a dry surface. His design is illustrated in Figure 1, Group 7(A).

The distribution of voltage over an individual insulator, insulator string or stack, under clean laboratory conditions, is determined by the inherent electrostatic capacity of the insulating shells or assemblies. In many applications of insulators this capacitance 'grading' is almost completely overruled by surface leakage through a conducting film of dirt and moisture.

An obvious alternative to capacitance grading is the use of resistance elements to control the division of voltage over the individual parts of a single unit or the various sections of a multiple assembly. Capable of contributing to such an approach, there is today a rapidly growing interest in semiconductors; a vigorous technology in silicon carbides and negative-temperature-coefficient resistors and a decade of experience in the use of semiconducting glazes.

Resistance grading of insulators by the use of semiconducting glazes has already shown considerable promise both in laboratory tests and in limited service applications. It is, at any rate, a relatively new science, largely unexplored. After 70 years of inquiry and experiment with capacitance graded units it may be assumed that this art has been liberally explored and that a more promising avenue should be sought for future research. In Figure 1 an attempt has been made to choose from many hundreds of insulator designs a few that represent diverse principles and to classify these according to type.

Classification of Fog Insulators

Oil-filled insulators illustrated in Group 1, Figure 1, do not promise a satisfactory solution of the surface leakage problem. Although the oil zone may be initially effective, it is soon contaminated by moisture and salts. Oil tends to creep over external insulator surfaces and to encourage collection of dust. Handling of the insulator is difficult and the angle of string inclination must be kept low to prevent loss of insulating fluid.

In insulators of this general type, designed to provide a protected area that repels moisture, the use of certain silicones or other surface treatments would be a more modern approach. Apparently there has not yet been developed a surface condition or treatment that will inhibit the deposition of dirt and moisture over a period of years.

Group 2 includes a standard suspension insulator. Because of its ruggedness, ease of manufacture and adaptability to close spacing, it has given an excellent performance in the majority of service applications. Attempts to modify this shape by extending the petticoats or the outer rim emphasize limitations of the standard disk. The deep sheltered corrugations collect dirt which cannot be cleaned out by wind or rain so that, eventually, the units may become less effective than standard insulators. In general, such modified units have a low wet flashover, a tendency towards flooding when used in long vertical strings and a very considerable handicap in regard to manufacturing cost.

Smooth disk units shown in Group 3 sacrifice both impulse and power frequency flashover strength in order to afford easier cleaning. In localities where cleaning by wind and rain is inadequate these insulators, when wetted, display vigorous corona around the pin and cap, particularly around the pin because of the absence of petticoats normal to the flange which limit streamer formation in standard disks. Such overstress near the terminals maintains dry areas and helps to prevent power frequency arcover but causes radio interference.

The insulators shown in Group 4 have been popular experimental types in areas where there is a large amount of rainfall and where the contaminant is a combination of salt, fog, and industrial dirt. The length of leakage path is not sufficient to hold leakage current at a reasonable level with all surfaces wet and contaminated.

Insulators in Group 5 combine features of Groups 2 and 4. They have the length of external surface greatly increased to limit leakage current; sheds are exposed to improve cleaning by natural agents. A considerable portion of sheltered surface is provided in which annular petticoating

Figure 1. Classification of fog insulators by design principle

may be used to reduce radial discharges from the insulator pin. Some designs from this group have given useful service in both coastal and industrial areas.

Insulators in which primary reliance is placed on dry zones maintained by fairly complete enclosure are shown in Group 6. Carried sufficiently far, this approach could theoretically guarantee dry areas great enough to hold a working voltage with neither electrical overstress nor excessive leakage current; actually, limitations of cost and space make it impractical to carry this principle to a fully satisfactory conclusion.

An attempt may also be made to maintain dry zones by artificial heating, with or without a decided measure of enclosure, as illustrated in Group 7. Complexity of design, power loss, and fragility are obvious limitations in this method of attacking the problem.

In Group 8 insulators, distribution of voltage is controlled by conducting, high resistance paths disposed in ribbon form or as an enveloping layer over the dielectric surface. They may be either temporary or permanent in nature. An attractive feature of temporary resistance paths (established only during adverse weather) is that a continuous power loss is avoided. Moreover, an insulator surface carrying leakage current in a water film is not likely, under any condition, to reach a temperature in excess of 200 degrees Fahrenheit. This desirable limitation does not necessarily exist when permanent resistors are built in or adjacent to the insulator surface.

Since conducting surfaces appear to be unavoidable in many types of service, the idea of making a merit of this necessity warrants serious consideration.

Recommendations for Deposit Conditions

A number of investigations of insulator performance under adverse operating conditions have been made by competent and diligent workers. In general, these investigators are reluctant to ascribe outstanding merit to a particular design. The following conclusions are typical:

"Early in the investigations described in this paper, it was realized that development of an insulator that would be the answer to the dust and fog problem would be possible in a short period of time."[4]

"There is no virtue in any particular shape except as it provides surface leakage resistance."[4]

"A surface leakage resistance of 11.0 inch-

Figure 2. Overstress on contaminated insulators

units per string appears sufficient for a steady voltage of 150-kv to ground."[1]

In terms of leakage distance this would be about 1.5 inches of leakage distance for each kilovolt of applied voltage, a figure that should be increased somewhat to take care of voltage surges.

From an English paper on insulator performance:[3]

"For use under highly polluted atmospheric conditions, the length of the leakage path—should be two inches per kilovolt of applied voltage."

"It is necessary in addition to ensure that the leakage path has other characteristics besides the necessary length."

Sheds not too closely spaced and arranged to contribute effective surface resistance.

"Investigations are being made to find a satisfactory method of incorporating stabilizing resistance within the units. When this has been achieved, the resulting insulator should have a very satisfactory performance in polluted atmospheres."

A distinction has been made between designs intended for industrial areas and those intended for sea coast deposits. For example:

"For industrial deposits a design should afford a maximum amount of upper surface which is washable by both wind and rain."[5]

"For salt deposits a design should supply a maximum amount of protected surface."[5]

After a desirable design has been chosen it may prove necessary to establish a periodical schedule of insulator washing. Though the preferred design must be washed eventually, it may have considerable merit if it can pass successfully, without washing, through one or more complete "fog" seasons.

Over-insulation has been proved a successful remedy in some areas, particularly where heavy industry is the source of contaminant. In this connection it is interesting to note that if large and small insulators have a similar geometry, the theoretical surface resistance does not increase with size. There are, however, many types of service in which the uniform film assumed in surface resistance formulae is not even approximated. Large units, though perhaps subject to greater maximum surge currents than small units, are better able to dissipate them and have the advantage of greater arc clearance.

Very frequently insulation on a line is changed to improve its performance and this change may be followed by a year or two of optimistic reports. Eventually the new units get dirty and the final result is disappointing. Since our increasing levels of industrial concentration are arousing widespread interest in the subject of this paper it is well to keep in mind the desirability of deferring judgment on the merits of insulators recently installed.

Figure 3. Leakage currents recorded on units with and without semiconducting glaze

Correlation of Field and Laboratory Studies

That weather of one sort or another is ever present and of almost endless variety, accounts for its popularity as a subject of conversation. It explains, also, a difficulty that is fundamental in laboratory tests made to evaluate the merit of contrasting insulator designs. The prospect of reproducing in a laboratory the infinite combinations of contaminant, air movement and precipitation is appalling. To consider only a few of these, fog may occur in still air or may be driven in by onshore winds with a velocity of 20 to 30 miles per hour.

Condensation takes place on surfaces sheltered against rain or fog. Rain may be beneficial or very harmful to the performance of insulators, depending on whether it appears as a quick vigorous shower that cleans exposed surfaces, or as a drifting drizzle that wets both exposed and hidden surfaces of the dielectric. Wet snow may pack inches deep in the crevices between shells or units and produce extremely high leakage surges over dirty insulators.

The impracticability of reproducing field conditions in the laboratory and the ingenuity of weather in contriving a previously unheard of condition suggests caution in recommending insulator types

Figure 4. Leakage surge mechanism, insulator with normal glaze and surface contamination

The film resistance is shown symbolically

Figure 5. Insulator with semiconducting glaze to improve voltage gradient

that might be vulnerable not only to flashover and a temporary outage, but to partial or complete failure. Certainly a great deal of experimental testing under actual service conditions should precede the recommendation of insulators employing permanent resistance grading, no matter how promising laboratory tests may appear.

Mechanism of Leakage Surge Flashover

Casual field observation shows that the voltage division over the several shells in an insulator stack or over the different units in a suspension string is by no means uniform. Due largely to the workings of chance, a few areas or units carry a large proportion of the voltage. This is illustrated in Figure 2. Insulator units that are arcing vigorously have high over-all surface resistance and carry an undue share of voltage except during that instant when a leakage surge takes place. In the intervals between surges inactive units support much less than their share of line voltage.

"Fog-box" tests of units with and without semiconducting glaze are shown in Figure 3. Both insulators were equally contaminated and were tested at 10 kv. No surges occurred on the treated insulator; it had a steady leakage current of 2.5 milliamperes.

Frequent leakage surges were recorded on the standard unit as shown in Figure 3A, B, and C. The surge time was only a small fraction of total elapsed time so that, although the upper limit of surge peaks was about 75 milliamperes, the average effective leakage current was comparable to that observed on the unit with semiconducting glaze.

A surge condition can exist for many hours and presents, therefore, an uneasy but recognizable state of equilibrium: the energy loss represented by the area under the leakage current curve, in combination with the amount of dirt on the insulator and the rate of moisture addition, contrives to maintain an adequate average level of surface resistance, and permits voltage to be carried without complete flashover of the string. Inactive units in the string that are dark and silent and coated with a continuous film of electrolyte develop only a small voltage drop while the leakage current lies near the base line but are effective in reducing voltage across active insulators as each surge peak develops. They may perform a useful function in preventing flashover, even though they do not carry their share of voltage during a large portion of the total time.

Instability of the moisture film on the insulator surface explains the recurrent surging that is observed. This is illustrated in Figure 4. Wet and dirty insulators are not uniformly conducting over the leakage surface. When one area of the insulator develops a thinner, high resistance film, a predominant amount of voltage appears across this drier area. If the voltage that appears is sufficiently great an arc short-circuits what was formerly a voltage-carrying surface and the ampere level reached is then limited largely by resistance of the remaining unshorted film. There is an extremely high momentary watt loss that burns back and thins out the film. This increased resistance quenches out the arc and reduces the leakage current to its lower envelope. An increasingly bad condition on the insulator string may be recognized by either a closer time spacing of the temporary surges or by surges equally spaced in time but of greater duration or magnitude.

Laboratory tests indicate that flashover of a string or stack is not likely to occur until surges reach a crest value in the order of 100 or 150 milliamperes. Under the majority of conditions, average leakage currents are far below this level and a possible solution of the problem is, therefore, to arrange a method of cutting down the high intermittent surges at the expense, if necessary, of raising the lower envelope of leakage current and the energy loss over insulation in fair weather. This result can be accomplished by building a slightly conducting film in the insulator surface separate from the deposited film of dirt and moisture and serving to level out the abrupt discontinuities that appear in the surface film. Figure 5 illustrates, in a qualitative manner, the function of a semiconducting glaze film. The height of the resistance symbol represents areas of high and low

resistance in the parallel films of contaminant and glaze.

Semiconducting glazes are in general use to distribute voltage stresses adjacent to insulator terminals. This original function has been extended to effect potential distribution over the whole insulator surface and has shown promising results in laboratory and field trials. It has been a subject of extensive research in Great Britain and several informative references are given at the end of this paper.[2,3,9]

Semiconducting Glazes

The use of semiconducting glazes, extending from terminal to terminal of an insulator is not a particularly new idea. Several patent applications are on record, applied for in the decade 1920 to 1930. A considerable time elapsed between conception of the idea and practical development of such glazes. Successful employment of semiconductors argues a level of process control not yet easily attained in the technical porcelain industry. Such glazes are influenced profoundly by minor impurities, small variations in kiln atmosphere and variations in composition of the clay body to which they are applied. To be commercially acceptable, a semiconducting glaze should have the following qualifications:

1. Approximate the hardness, chemical resistance, and strength of a normal glaze.
2. Permit the use of existing manufacturing equipment.
3. Yield a high percentage of acceptable product.
4. Show long term stability under voltage.
5. Carry much greater than normal currents for short intervals of time without excessive heating or burn-out.
6. Resistant spalling from the sudden cooling of hot surfaces.
7. Allow electrical tests to establish the dielectric strength of components and assemblies.

Ordinarily, semiconductors have a decided negative temperature coefficient, a mixed blessing which contributes to their value in stabilizing surface films of dirt and moisture, but renders them liable to self-destruction in their effort to effect compensation during prolonged and unexpectedly severe conditions of service. In order to anticipate such severe conditions of service, there is an urgent need of accurate information about the nature and magnitude of energy loss over insulators now in use in sea-coast, railway, and heavily industrialized areas. If this information can be acquired for the insulator designer, and if he may also choose from a wide variety of conducting glazes, he should be able to contrive insulator contours peculiarly suitable to resistance glaze application and particularly fitted for a known type of service.

To supplement laboratory tests on artificially contaminated insulators, a permanent outdoor rack (Figure 6) has been set up and a variety of insulators energized at 44 kv. Each string is connected to ground through a surge counter circuit (Figures 7 and 8) which permits the insertion of auxiliary instruments.

Figure 9, a 14-month record of surge counts, illustrates the unpredictable nature of leakage current surges. A single period of moderate rain contributed 60 per cent of the surges recorded against type "E" yet only a very modest percentage to types "A" and "C" which are similar in design.

Conclusions

1. Wet and dirty insulators distribute voltage in proportion to surface resistance.
2. Of insulator types employing capacitance 'grading,' for exposure to sea coast or industrial contamination, some of the designs from Group 5, Figure 1, present a useful combination of leakage distance, drip-clearance, ruggedness, and self-cleaning.
3. Inbuilt capacitances are capable of controlling completely only mild exposures to dirt and moisture.
4. Inbuilt resistance promises a more powerful control at the expense of fair-weather power loss and some increase in the hazard of insulator damage.
5. Specific information is needed about the nature and magnitude of energy loss over various styles of insulators in a variety of service conditions. Surge measuring equipment is being installed on utility properties for this purpose.
6. Semiconducting glazes should be developed and their successful application

promoted by an increasing measure of raw material and process control.

7. Continued co-operation of insulator users to determine both the risks and possibilities offered by this avenue of development can contribute greatly to advancement in the art.

Discussion

Bradley Cozzens (Department of Water and Power, Los Angeles, Calif.): The paper as presented by Taylor gives a brief and concise history of the mechanism of breakdown of contaminated insulator surfaces, and points out the extended research and development that has been conducted over many years on shapes and methods of supporting insulators to relieve the difficulties occasioned by contamination.

By way of comment, the insulator shown as item (B) of Group 6 in Figure 1 of Taylor's paper, which was developed largely in response to the need for an insulator which would prevent pin burning in a seacoast area, has proved relatively satisfactory and has accomplished the end for which it was designed. The Department of Water and Power, Los Angeles, Calif., has considerable 4,800-volt ungrounded delta feeders operating adjacent to the seacoast with heavy salt contamination. This insulator, with a slight modification, carrying a drip ring at the midsection, is used almost exclusively in such areas. The insulator shown as item (E) of Group 6, is approximately the design which was suggested as a result of the test procedures reported in another paper.[1] The close coupling of this labyrinth makes it very difficult of assembly, and once contamination would occur it would be practically impossible to clean such an assembly without complete dismantling. However, there is definite precipitator action which should keep the inner portions of this insulator clean over an extended period of time, as well as preventing the accumulation of moisture within the area adjacent to the cap and pin.

Referring to Figure 4 of the paper, I have some question as to the area marked "sheltered area near insulator pin." If I interprete the curve properly, this would indicate that little or no contamination occurs in this area and, therefore, the resistance of this area is particularly high. Studies conducted in connection with dust depositing, as shown in Figure 4 of the paper by Cozzens and Blakeslee,[1] with particular reference to curves 3 and 4, indicate that the accumulation of dirt or dust on and adjacent to the pin, and immediately adjacent to the cap except for the area shielded by the cap bead, is appreciably greater than that over the remaining surface of the insulator. Checks of voltage distribution over the insulator surface, curve 3 of Figure 4, shows clearly that the contamination is appreciably greater adjacent to the pin than in other areas. I believe that the results as indicated in Taylor's paper probably were due to the fact that dust was not deposited in sufficiently high velocities, or possibly was deposited while the insulators were not energized, either of which will cause the condition as shown.

In the author's Conclusion (5), he states that "Specific information is needed about the nature and magnitude of energy loss over various styles of insulators in a variety of service conditions. Surge measuring equipment is being installed on utility properties for this purpose." It was found during the laboratory tests on insulators that the surge periods of high current, though for the period of time which they existed contributed appreciably to the heating of the insulators, were only partially responsible for the total heating which occurred. Leakage current of the order of two to five milliamperes may exist continually and, except in very heavy fog, with appreciable movement so that moisture is driven against the face of the insulator, the surges of highest current occur at relatively infrequent intervals.

On the initial application of fog after an accumulation of dust, if such application is quite sudden, the leakage currents are very high, developing first of a continuous nature and as units dry in the high current density area becoming more of the nature as indicated in Figure 2 of paper by Cozzens and Blakeslee.[1]

It appears that in order to get a proper answer to the energy loss some watt integrating device would be necessary. The recording of surges as could be seen from Figure 2 would be of little value since many of these surges exist for only one or two cycles, while others exist for as much as 60 or more cycles. The continuous current which exists between the high current surges also must be included in the determination of over-all heating of the insulator surface. The tests that have been conducted by the Department of Water and Power thus far have not attempted to determine accurately the power loss for current values below three milliamperes. This current flow is relatively continuous. In the range above this minimum current value, the intermittent arcing contributes a relatively small amount of energy loss. Determinations of some ten tests showed a variation in average loss from 18 to 175 watts. This, of course, was superimposed upon the loss resulting from the continuous low current leakage.

Reference

1. See reference 4 of the paper.

J. J. Taylor: The author wishes to thank Cozzens for his interesting discussion.

Insulators of both types *6-E* and *6-F* have had periods of trial installation on west coast lines. Eventually sufficient dirt was deposited on interior surfaces to make operation of the insulators audibly noisy. Condensation in the interior, on the dirt film, resulted in low amperage internal discharges and the hollow shapes amplified the noise.

Regarding the sheltered area shown in Figure 4 of the paper, our inquiry confirms Cozzens' observation that dirt deposit is heaviest near the pin; the high resistance indicated for this surface is the net result of moisture plus contamination and controlled largely by the thinness of the moisture film.

From surge measuring equipment we do not expect to get a direct measurement of energy loss but rather a series of observations that, by correlation with similar records made in the laboratory and with more delicate equipment, may permit estimates of contamination severity.

A New Distance Ground Relay

S. L. GOLDSBOROUGH
MEMBER AIEE

DISTANCE-type relays have been used successfully for many years to protect against phase faults on transmission lines. However, distance relays to protect against ground faults in the same satisfactory manner as for phase faults have not been generally available. Some attempts have been made to adapt distance phase relays for operation on ground faults. In a small number of cases the results have been reasonably satisfactory but, in general, the fundamental limitations pertaining to these relays have prevented their widespread application. The new relay discussed here is an attempt to satisfy the long felt desire for a satisfactory distance ground relay.

It should be interesting to briefly review some of the factors involved in the design of a distance ground relay. Since a phase distance relay uses delta line voltage and delta line current, it no doubt occurs to many engineers that a ground distance relay would operate on line-to-ground voltage and line current. This, however, is not a valid conclusion because ground faults introduce a factor not existing on phase faults which must be considered. The additional element to be considered is the fact that, in general, the zero sequence impedance of a transmission line is not equal to the positive-sequence impedance. This means that, as the distribution of the positive, negative, and zero sequence currents varies because of changes in system connections outside the protected line section, the ratio of line-to-ground voltage to line current changes thus causing a variation in the ohm reach of the relay. This can be seen more readily if we express the quantity which the relay would be required to measure in symmetrical components. Referring to Figure 1 (a) the impedance at the relay location R is:

$$\frac{I_1Z_1+I_2Z_2+I_0Z_0}{I_1+I_2+I_0} \tag{1}$$

assuming Z_0 to be $3Z_1$ it is easily seen from this that, as the relative values of the positive, negative, and zero sequence currents are changed in a certain fashion the corresponding voltage drops do not change in the same manner. For instance, if we change the external system connections as shown in Figure 1 (b) where all the positive and negative currents come from the generator through the relay and all of the zero-sequence current comes from the right-hand grounded transformer bank, it can be seen that the relay current magnitude is reduced to two thirds, whereas the voltage is reduced to two fifths of the former value. Thus the line to ground voltage to line current ratio has been drastically altered by system changes external to the line section. On the other hand, a phase relay responds to the ratio

$$\frac{I_1Z_1+I_2Z_2}{I_1+I_2}$$

and here it is seen that external system connections cannot affect this ratio. The positive-sequence impedance of the line section is always equal to the negative sequence and, in general the positive and negative sequence fault currents are nearly equal. However, if the relative values of I_1 and I_2 change the relative values of I_1Z_1 and I_2Z_2 will change in exactly the same manner so that the voltage to current ratio is not changed. This same situation would apply on ground faults if the zero-sequence impedance were equal to the positive-sequence impedance. However, the zero sequence is nearly always considerably higher than the positive-sequence impedance and this has the effect of adding an extra voltage drop during ground faults over and above the phase fault value which is not compensated by an additional current component. If Z_0 were equal to Z_1, the impedance on a single-phase-to-ground fault would be

$$\frac{I_1Z_1+I_2Z_1+I_0Z_0}{I_1+I_2+I_0}=\frac{3I_1Z_1}{3I_1}=Z_1 \tag{2}$$

but, assuming $Z_0 = 3\,Z_1$ the expression is

$$\frac{I_1Z_1+I_2Z_1+I_0Z_1+2I_0Z_1}{I_1+I_2+I_0}=\frac{5Z_1}{3} \tag{3}$$

Thus the additional voltage drop $2\,I_0Z_1$ has been created solely because Z_0 is 3 times Z_1 instead of equal to Z_1 but no additional compensating current has appeared so the indicated impedance is different. Inspection of the above expression indicates that if the current $2\,I_0$ be added to the denominator the expression would reduce to Z_1. Further consideration will reveal that for the general case an additional current I_0 modified by a factor $\frac{Z_0-Z_1}{Z_1}$ must be added to the line current operating the relay in order to compensate for the additional voltage drop caused by that part of the zero sequence line impedance which is in excess of the positive sequence impedance. The general expression for the relay on the grounded phase and neglecting fault resistance is, therefore,

$$\frac{E_{LG}}{I_{line}+\frac{(Z_0-Z_1)}{Z_1}I_0}. \tag{4}$$

A distance relay which utilizes the above quantities is essentially a phase re-

Figure 1. Single line diagram of simple system

Paper 48-260, recommended by the AIEE relay committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted July 19, 1948; made available for printing August 27, 1948.

S. L. Goldsborough is with the Westinghouse Electric Corporation, Newark, N. J.

lay with a current compensation added to enable it to function properly on ground faults as well as interphase faults. Such a relay has been available for a number of years but its application has been very limited because of certain fundamental characteristics.

It is quite essential that a ground relay respond to reactance rather than impedance, because the amount of fault resistance liable to be encountered on ground faults is much higher than is present on interphase faults, so that an impedance relay ohm reach would be too drastically reduced. The requirement that the relay measure reactance introduces a severe limitation which comes about solely because of the characteristics of a reactance element. It is well known that a reactance element operating on line current will readily trip during normal load conditions, since the apparent reactance value presented to the relay may be a low positive value, a zero value, or even a negative value. For this reason it is necessary to employ an impedance element to supervise the reactance element since the apparent impedance as seen by the impedance element is always positive on faults and all load conditions. Since fault resistance values on ground faults are relatively high, it is necessary to set the supervisory impedance element for a long reach. A long enough reach on the impedance element to encompass the maximum fault resistance often means that the impedance element responds to maximum load current. Since response to load currents is not permissible, it is necessary to shorten up on the impedance element and be content to forego tripping on some high resistance faults. The limitation on load current is not too serious since a satisfactory discrimination between fault current and load current could be obtained except for the longer line sections. However, it turns out that it is necessary to make a discrimination between fault magnitude of current on the unfaulted phases and fault current on the faulted phase. On an actual system wherever it is possible for positive and negative currents to flow from one generating source to a ground source located elsewhere, there will be a flow of fault current on all 3-phase conductors for a single-phase-to-ground fault. This state of affairs is quite common and occurs in varying degrees on nearly all power systems. Figure 1 (b) is an example of this condition, positive and negative sequence currents flowing on all three conductors from the left-hand end and zero sequence currents flowing on the three conductors from the right-hand end. It is obvious that the supervising impedance elements in all three relays will be actuated under these conditions and thus the reactance element in at least one relay on the unfaulted phase will overreach and trip for external faults. If the impedance element's reach is restricted enough to prevent its operation under this condition then on the faulted phase it would not reach far enough to allow the reactance element to cope with a reasonable amount of fault resistance.

Figure 3. Schematic connections of phase selector elements

The particular ground relay described in reference 2 was beset by another difficulty. As described in reference 1, a line current compensated ground relay being essentially a phase relay will respond on 2-phase-to-ground faults. For instance, on a B-phase to C-phase-to-ground fault both the B- and C-phase relays respond, but each relay will either overtrip or undertrip in opposite fashion depending upon whether the phase-to-phase fault resistance is smaller than the phase-to-ground resistance or vice versa. Since it is impossible to predetermine what state of affairs will exist, it was necessary to block tripping by means of the operation of two or more supervising impedance elements. This, of course, means that all tripping on bona fide single-phase-to-ground faults where fault current occurs on all conductors is blocked. If, for some reason, it had not been necessary to block tripping on 2-phase-to-ground faults one would have merely exchanged the failure to trip at all for the failure to confine tripping to faults inside the line section.

The foregoing discussion has brought out the main difficulties involved in attempting to adapt a phase relay to perform correctly on ground faults. It is to be noted that the trouble is caused by the use of a reactance element operating on line current. It would, therefore, appear that a reactance relay operating on zero sequence current alone would avoid the difficulties mentioned previously. Furthermore, the use of zero sequence provides an automatic fault detector action since current is present only during fault conditions. A supervising impedance element is thereby dispensed with. Also, there is only one zero sequence current, therefore, as far as the current circuit is concerned, only one relay is needed to provide ground protection on all three phases.

Referring to Figure 1 and equation 1, it can be seen that if we eliminate the positive- and negative-sequence currents and also the positive- and negative-sequence voltage drops from the relay to the fault the expression reduces to

$$\frac{I_0 Z_0}{I_0} = Z_0$$

Figure 6. Conditions during 2-phase-to-ground and single-phase-to-ground faults

where Z_0 is the impedance from the relay to the balance point. The positive-and-negative-sequence voltage drops can be eliminated from the line-to-ground voltage by passing the positive-and-negative-sequence secondary currents through a suitable compensator which will develop a voltage representative in magnitude and phase angle of the primary positive-and-negative-sequence voltage drops. This type of compensation is called voltage compensation and is covered in complete mathematical terms elsewhere.[1]

Since there are three line-to-ground voltages, it is necessary to subtract the positive-and-negative-sequence drops in each phase from the corresponding line-to-ground voltage. Therefore, from the standpoint of the voltage circuit, three ground relays or their equivalent are required. However, it appeared to be very desirable to take advantage of the phase selector relay developed for single-pole tripping[2] to switch the proper faulted phase-to-ground voltage into the voltage circuits of a single ground relay. This type of phase selector operates on the phase shift between the negative-sequence and zero-sequence currents depending upon which phase conductor a ground fault occurs. It is very sensitive and has given a good account of itself during several years of actual service.

Briefly the phase selector operates as follows. Figure 2 shows the phase shift among the three sequence components for single-phase-to-ground faults on different phases. It will be noticed that the zero-sequence component rotates around a given phase of the negative-sequence system in 120 degree steps. For instance, on a phase-A-to-ground fault the zero-sequence current is equal to and in phase with phase A of the negative sequence. This is, of course, on the basis of the total fault current. For a fault on phase B the zero-sequence component is in phase with the B-phase negative sequence, and, similarly, for a C-phase-to-ground fault the zero sequence is in phase with the C-phase component of the negative sequence. Therefore, a selector element utilizing zero- and negative-sequence current will act in one direction for phase-A-to-ground faults but will act in the opposite direction for ground faults on B-and-C-phases. Thus, if a directional element with watt-element characteristics is supplied with the zero-sequence current in one coil and the phase-A-component of the negative-sequence current in the other coil, then on a phase-A-to-ground fault this element will have maximum torque in the contact-closing direction. For a fault on phase B the zero-sequence current leads phase A of the negative sequence 120 degrees, and for a fault on phase C the zero-sequence current lags phase A of the negative sequence by 120 degrees. The element will, therefore, have torque in the contact-opening direction for phase-B and phase-C ground faults. If another similar relay element is used with its corresponding coil energized by the zero-sequence current, but its other coil energized by the phase-B component of the negative sequence instead of the phase-A, then, for faults on B phase it will be operating at maximum torque and will close its contacts but will have reversed torque for ground faults on phases A and C. Likewise, a third element energized by zero-sequence current and the phase-C component of the negative-sequence current will close its contacts for phase-C-to-ground faults, but open its contacts for faults on the other two phases. The schematic connections for this relay are shown in Figure 3.

The phase-selector relay consists of three elements similar to the conventional directional element. The polarizing coils of all three elements are energized by the zero-sequence current. The other coil on each element is energized by a component on the negative-sequence current obtained from the 3-phase negative-sequence filter. This filter is so connected that the phase-A component of the negative-sequence system is supplied to the phase-A element, the B component supplied to the B element and the C component supplied to the C element.

The complete ground relay equipment consists of a phase selector relay, a three zone reactance ground relay, an auxiliary unit, and a negative sequence network. Figure 3 shows schematically the selector element connections. Since more contacts are required than can be efficiently provided on the sensitive selector elements, small telephone-type relays are utilized. These relays are energized on direct current by the selector element contacts. The selector relay consists of the three negative-zero sequence selector elements, three auxiliary relays, and three compensators designed to provide compensation for the second and third zone elements of the reactance relay.

The reactance ground relay consists of three beam-type reactance elements, a directional element, and a synchronous timer. The trip circuit connections are shown in Figure 4. The auxiliary unit consists of three compensators associated with the first zone reactance element, and three air-gapped mixing transformers to impart the reactance characteristic to the beam elements.

Figure 5 shows the schematic connections of the compensators and one reactance element.

The zero-sequence current is removed from the three main current transformer leads by the 15/5 ratio auxiliary trans-

Figure 7. Phase selector relay

formers, leaving only the positive-and-negative-sequence currents to pass through the primaries of the compensators. These compensators consist merely of air-gapped stepdown current transformers. The voltage induced in the secondary winding is almost 90 degrees lagging the primary current. The secondary winding is actually shunted by a variable resistor (not shown) so that, by adjusting the primary and secondary taps and this resistor, the voltage across the secondary can be made exactly proportional to, and the same phase angle as the voltage drop produced by the positive-and-negative-sequence current flowing in the line impedance between the relay and its balance point. The compensator voltage subtracts from the potential transformer line-to-ground voltage so that the resultant voltage applied to the relay coils is the zero-sequence voltage drop $I_0 Z_\phi$. The particular compensated phase-to-ground voltage to be applied to the element is, of course, determined by the action of the phase selector auxiliary contacts T_A, T_B, and T_C, Figure 3.

In order to obtain a reactance characteristic from a beam-type element, it is necessary to balance the vector sum of the current and voltage on the operating or contact end of the beam against a voltage restraint on the back end of the beam. Also, the voltage ampere turns on the operating end must be shifted 90 degrees leading or the current lagged 90 degrees with respect to the voltage, and furthermore, the mechanical pull of the operating end voltage without current must equal the restraint voltage pull. These requirements are met in the circuit shown in Figure 5. The induced voltage in the secondary of the mixing transformer lags the primary current by 90 degrees and this current derived voltage and the compensated line-to-ground voltage are directly combined in the single operating coil on the reactance element. It is permissible to mix the current and voltage circuits in this fashion, since the current from the current circuit is stepped down to the order of magnitude of the current produced by the voltage circuit and the secondary impedances of the mixing transformer, the compensators and the potential transformers are relatively negligible.

During normal unfaulted conditions the reactance element is totally de-energized. When a single-phase-to-ground fault, for instance, a phase-A-to-ground fault occurs the negative-zero sequence phase selector operates to close the S_A make contacts while the S_B and S_C back contacts remain closed, thus energizing the T_A auxiliary relay. This connects the phase-A-to-ground compensated voltage to the element. The zero-sequence current, of course, appears in the element the moment the fault strikes since there is no switching in the current circuit. During the time interval after the fault and before one of the contacts T_A, T_B, or T_C has closed, the only path for the zero sequence current is through the operating and restraint coils in series. This current produces a net restraining torque since the number of turns in the restraint coils is larger than the number of turns in the operating coil. As soon as one of the selector contacts is closed, the proper

Figure 8. Reactance ground relay

voltage is established across both coils and a path through the compensator and potential transformer is established which allows the proper zero sequence current to flow through the operating coil.

The directional element utilizes zero sequence in one coil and the proper uncompensated line-to-ground voltage as determined by the action of the phase selector. These quantities rather than zero sequence current and voltage have been used in order to overcome a characteristic of the phase selector on two phase-to-ground faults. On a 2-phase-to-ground fault, for instance B to C to ground, the zero sequence current is in

Figure 9. Auxiliary unit for ground relay

phase with the phase A negative-sequence current which is the same relation as is obtained on a phase-A-to-ground fault. The phase selector, therefore, applies the phase-A voltage to the relay on the B-phase to C-phase-to-ground fault. As will be seen from Figure 6, the zero-sequence current in this case is leading the phase-A to-ground voltage and this, of course, causes the reactance element to overreach considerably. Undesirable tripping because of the overreach of the reactance element is prevented by the fact that when the phase-A voltage is applied to the reactance element, another contact (not shown) on the auxiliary relay T_A applies the phase-C-to-ground uncompensated voltage to the directional element. As will be seen from Figure 6, this places the current and voltage on the directional element in the nontrip area. However, on a bona fide phase-A-to-ground fault the same voltage is applied to the directional element, but tripping is permitted because the zero-sequence current has reversed about 180 degrees with respect to the phase-C-to-ground voltage. Thus the relay B, Figure 6 (a), is prevented from tripping for 2-phase-to-ground faults beyond the far bus. Considering now the relay A on the other side of the bus, it is obvious that its directional element will close contacts, since it receives a zero-sequence current reversed from that in relay B. However, its reactance element will measure positive reactance and will receive the unfaulted phase-A-to-ground voltage so, in general, it will not trip on double ground faults beyond bus 2. A close-in 2-phase-to-ground fault as at X may aggravate the situation considerably since there may be enough ground current through the relay A to trip the reactance element even though it is measuring reactance correctly and is restrained by an essentially uncollapsed voltage. When this condition is reached, it can be very simply corrected by the use of an additional directional element energized by zero-sequence current and voltage. However, it is felt that in the great majority of actual applications the use of zero-sequence current and line-to-ground voltage on one directional element to provide a power directional sense and a discrimination between single- and 2-phase-to-ground faults is all that is necessary.

The ground relay equipment previously discussed utilizing a negative-zero sequence phase selector is intended primarily for application on essentially solidly grounded systems. On systems grounded through appreciable values of impedance a voltage-type selector can be used to advantage. Impedance grounded systems generally produce a considerable neutral shift, thus, on single-phase-to-ground faults, the faulted phase to neutral voltage drops to a relatively low value while the other two voltages rise considerably above the normal line to neutral value. A voltage phase selector utilizing one of the unfaulted line-to-ground voltages as an operating voltage balanced against the faulted voltage as a restraint voltage provides a very positive means of selecting the faulted phase.

A reactance ground relay scheme utilizing voltage phase selector elements has been given extensive laboratory and field tests and has performed satisfactorily. The negative-zero sequence phase selector has, of course, already proved highly satisfactory in connection with single pole tripping and reclosing equipment. It is felt that the new reactance ground relay combined with the sequence operated selector or the voltage selector will open up many new applications for distance relays.

Discussion

W. A. Lewis (Illinois Institute of Technology, Chicago, Ill): The paper by Goldsborough represents the culmination of a very long development program. Having been connected with the early stages of this development, I would like to take this opportunity to review briefly part of its early history. The basic principles upon which this relay is based were described in a paper presented in 1931.[1] Many of the principles incorporated in the relay were described in a paper presented before the AIEE in 1932.[2] At the time these two papers were presented the AIEE did not publish in the Transactions, papers which were considered to be of transitory interest. However, at the request of the relay committee, the first of these two papers was revised and re-presented before the AIEE in January 1947, and published in the Transactions for 1947.

The basic difficulty encountered in the early developments of a relay based on these principles was that the measurement of distance by means of a reactance relay was dependent upon the fault resistance during a double-line fault because the current in the fault resistance was not in phase with the current in the relay. One of the relays on one of the faulted phases would indicate that the fault was too close, and the other would indicate that it was too far away. If the resistance in series with the phase conductors predominated, one relay would overreach, and if the resistance in the ground or neutral connection predominated, the other relay would overreach. The only sure method of preventing false operations thus was to prevent either relay from operating on a double-line to ground fault. Methods for doing this which were then available were quite complex and were thus not attractive.

Meanwhile, the development of carrier-current relaying offered sufficient advantages that the carrier relays were developed, and the distance ground relay was pushed less actively. With recent increases in cost, the cost of carrier-current equipment has risen sharply, so that further study of a distance ground relay is now highly justified.

The development of a phase selection

method in connection with single-pole switching for ground faults now provides a satisfactory method of selecting only the faulted phase for a single-line-to-ground fault and for preventing operation of the relay on other types of fault.

The new relay described in the paper seems to overcome all of the previous disadvantages, and to offer considerable promise for a satisfactory high-speed ground relay which is selective and does not change its balance-point appreciably for a large change in generating capacity. Thus, more widespread application of the distance ground relay should now be possible.

A possible extension in this development should also be mentioned at this time. In the relay described by Goldsborough, tripping is accomplished by zero-sequence current, and the components of voltage drop produced by positive-and-negative-sequence currents are eliminated by the compensators. This arrangement will usually prove most satisfactory. However, for ground protection of a circuit at the terminal where a source of ground current cannot always be assured, this relay or any other ground relay responsive to zero-sequence current cannot be depended upon. An alternative arrangement described in reference 1 of the paper is to use the phase current for tripping, and to remove the voltage drops produced by zero-sequence currents from the restraining voltages by means of zero-sequence compensators. If the development described in the paper finds adequate application and use, the alternative development just mentioned may be justified as the solution of special cases not otherwise taken care of. For such a scheme, the selection of the proper phase relay to trip could usually be made by means of a voltage selector.

2. A HIGH SPEED RELAY FOR SHORT LINES, S. L. Goldsborough, W. A. Lewis. ELECTRICAL ENGINEERING, volume 51, 1932, pages 157–60.

A. R. van C. Warrington (General Electric Company, Philadelphia, Pa.): Goldsborough has shown in a very interesting paper how one distance relay can provide ground protection for a 3-phase terminal, but one wonders whether the cost of the distance relay, the selector relay, and the auxiliary box is not comparable with that of three ground distance relays.

The relay system is by no means new, as the reference numbers 1 and 4 of the author's paper will indicate. A single *GCX* reactance relay with the same potential compensation as the authors describe has been in service since 1942 with a perfect record of correct operation.

A similar scheme was used for phase distance relays in Germany before the war wherein the vector difference of two of the phase currents was supplied to the relays and the potential was switched between phases by a selector relay, suitable compensation being provided for the double current effect of a fault involving both the relay phases.

In ground distance relays current compensation is preferable in some cases and potential compensation in others. Potential compensation is preferable only when there is a large amount of reactive current transfer but has the disadvantage of less sensitivity since the relay gets only a fraction of the phase-to-neutral voltage

The idea of having a phase selector which can go wrong on double ground faults and then correcting it by adding a zero sequence directional unit seems to be a rather oblique approach. It would be better to use a correct phase selector in the first place.

Eric T. B. Gross (Illinois Institute of Technology, Chicago, Ill.): Though the basis for distance relaying of single circuit lines has been known for some 20 years, not many applications have been made in the United States. However, a small number of installations has been in operation quite successfully and some of them were described in the literature.[1,2] Since the majority of faults are grounds, this problem deserves wider publicity and Goldsborough's fine paper is another valuable step ahead in the right direction.

The current compensation discussed in equation (4) of the paper seems to have been introduced first in France in 1929 and has been used abroad successfully in many resonant grounded[3] systems. The difficulties encountered with double-line-to-ground faults in effectively grounded systems do not exist in resonant grounded systems since double-line-to-ground faults are simply phase-to-phase shorts. This may be the reason for the wider applications of current compensation schemes abroad when ground fault neutralizer application is the preferred practice. It may be mentioned that schemes were developed to protect against consequent double ground faults (that is, one ground on one phase at one location and subsequently a second ground on another phase at a different location) selectively by switching off one of the two grounds only in order to get all the advantages which may be gained from resonant neutral grounding.[4,5,6]

Carrier Channels for Telemetering

T. DeWITT TALMAGE
MEMBER AIEE

Synopsis: This paper describes design engineering considerations involved in the application of 68 carrier current terminals at 25 locations used to establish the major portion of a 6,500-mile telemeter and automatic load-frequency control system. Both telephone-line and power-line carrier equipment is used with the latter predominating and consisting of four general types: keyed continuous wave; multitone amplitude modulation; multitone frequency modulation; and frequency shift. The quantity and direction of power flowing in 17 major transmission tie lines between the Tennessee Valley Authority (TVA) and surrounding power systems are telemetered an average distance of 172 miles to an operating office where tie-line loadings are totalized. Based on this net interchange quantity, deviation, from-schedule control signals, on a time-duration impulse basis representing kilowatts, are sent by a frequency-shift power-line carrier system to a total of 12 hydroelectric plants, to automatically regulate the governors of generators in response to load and frequency changes on the tie lines within the limits set by scheduled water releases which are co-ordinated with other objectives of the TVA. Two separate master control carrier channels are used with one serving seven and the other eight hydroelectric generating plants. To provide operating flexibility, three hydro plants are common to both carrier control channels.

It is the purpose of this paper to review the dominant engineering considerations included in the planning and design of a 6,500-mile telemeter and automatic load-frequency control system required to secure maximum benefits from 17 inter-system tie lines located at 12 different geographic points in the Tennessee River valley region as shown in Figure 1.

The electric power systems stretching from the Great Lakes to the Gulf of Mexico and from west of the Mississippi River to the Carolina coast, serve the South Atlantic and central areas of the United States and normally operate interconnected and in parallel. This integrated power pool is made up of 84 companies having a total installed generating capacity of about 18,000,000 kw, with a peak load approaching close to this same value. The TVA system is centrally located in this network and its generation, furnished by 27 major plants,[1] shown in Figure 1, represents about one-eighth of the total. From the standpoint of water releases and power dispatching, the operation of five additional major generating plants, owned by the Aluminum Company of America, has been co-ordinated to provide maximum utilization of water power of the region. These plants have an installed capacity of 311,120 kw and their locations are included in Figure 1. A peak-hour demand of 2,457,000 kw was recently handled by this joint system which now has an installed nameplate capacity of 2,571,000 kw. The combined power system operated under direction of the TVA represents about 14 per cent of the total interconnected pool capacity.

The basic reasons for interconnections are well recognized and can be summed up in two categories: improvement of continuity and quality of electric service; and maximum economic over-all operation of facilities furnished by the participating beneficiaries. Both of these desirable results redound to the benefit of the ultimate users of electric power service. Hourly schedules of energy transfers between systems are jointly established in accordance with applicable contracts to secure mutually advantageous results. For efficient control of generation and schedules, it has been found imperative to furnish the power system load dispatchers with a clear picture of the power flowing at vital points. This is especially true if rapid recovery from system troubles and disturbances is to be expected under present heavy load conditions.

Paper 48-262, recommended by the AIEE carrier current committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948 and at the Southern District meeting, Birmingham, Ala., November 3-5, 1948. Manuscript submitted August 2, 1948; made available for printing September 17, 1948.

T. De Witt Talmage is principal communication and signal engineer with the Tennessee Valley Authority, Chattanooga, Tenn.

Statement of Problem

The main parts of the primary problem of realizing the foregoing essential results were:

1. To bring to a central operating office an indication of kilowatts flowing into or out of the TVA's system from each of 12 principal power interchange points, in the most economical fashion.

2. To provide at the central operating office a flexible arrangement for totalizing individual interchange readings by companies, areas, or a combination of both.

3. Based on one or more selected tie-line loadings, to send a master control signal from the central operating office to 12 hydroelectric generating plants, three of which are owned by two interconnected companies, so that existing control apparatus could automatically regulate the generation of power to compensate for variations in the TVA load.

While both (1) and (2) were installed in gradual stages, part (3) was divided into two separate steps. The first step, based on using a minimum of new material, consisted of installing equipment to transmit one master control signal by power-line frequency-shift carrier equipment to seven hydroelectric generating stations, and was placed in service during World War II in order to further the war effort by loading lines to the maximum capacity.

The second step consisted of providing a second master load control signal by a crystal-controlled frequency-shift carrier channel which could function simultaneously with, but independently of, the first in such a fashion that the TVA power system could be operated in two sections. Both steps provide a system which allows any one or more of a total of 46 units installed at 12 generating plants, arranged as described in the section headed Load-Frequency Control Channels, to be used for the automatic regulation of power interchange. These

generating units represent about one-half of the installed capacity of the combined TVA-Alcoa power system.

The TVA'S 6,666-mile transmission system,[2] 293 substations, and 12 power interchange points are shown in Figure 1. Nine of these interchange points involve one transmission line each, two points involve two lines each, and one point consists of four lines. Ten of these 17 transmission lines are rated at 161 kv, five at 115 kv, and one each at transformation points of 132- to 66-kv and 110- to 66-kv.

The average air-line distance from the power system operating office at Chattanooga, Tenn., to the intersystem metering points is 136 miles, the closest being six miles away and the farthest 266 miles. An important objective was to route the telemeter circuits by the most direct and reliable paths. In the case of several tie-line indications, it was desired to route them by the way of strategically-located generating plants, especially suitable for controlling generation such as Wilson, Watts Bar, and Norris hydroelectric generating plants so that automatic control direct from these tie-line loadings would be available when needed. Also, the Wilson Dam operating office was to be furnished with tie-line interchange readings necessary to keep this point continuously informed of the loading on certain intersystem power circuits. As the system was finally laid out, the average length of the 12 tie-line telemeter channels was 172 miles, only 26 per cent longer than the air-line distance. Ninety-three per cent of this mileage is routed over the power-line conductors by carrier channels, the balance being by telephone cable circuits and carrier over open-wire telephone circuits.

The telemetering system in Figure 2 shows the detailed connections of all channels from the metering equipment to the final output of the telemeter receivers into the load-frequency controllers at ten regulating plants. The frequency-shift load-control receiver at Alcoa substation makes automatic tie-line control available to two of Alcoa's hydroelectric generating plants.

Because of shortages of critical material during the war period, maximum use was made of all existing equipment. Five carrier pilot relay channels were in service between points over which one telemeter-reading was required to be transmitted. These ten pilot relay sets were used to transmit a telemeter signal with the protective relays taking precedence in use of the channel. The output of these carrier pilot relay transmitters is approximately 20 watts each and the average length of the channels is 62 miles. A typical power-line carrier pilot relay transmitter-receiver terminal used jointly for telemeter and protective relay purposes is shown in Figure 3.

Frequency-Shift Telemeter Channels

In four cases of transmitting one telemeter reading over distances varying from 80 to 100 miles, power-line carrier frequency-shift channels were established following World War II for one or more of the following reasons:

1. No carrier pilot-relay channel was available.
2. Installed carrier pilot-relay channel was already being used for a second service which conflicted with the addition of a telemeter channel
3. Low carrier transmitter power (two

Figure 1. TVA power transmission and distribution system showing 17 major intersystem tie lines at 12 geographical locations

Identification of power interchange points by circled letters corresponds to telemeter code used in Figure 2

watts) was needed to eliminate interference with existing or proposed channels.

Five additional frequency-shift carrier channels are used to telemeter five individual interchange readings from four of the TVA's switchyards to the Commonwealth and Southern Corporation's system[3] and to the Arkansas Power and Light Company. This type of carrier equipment was chosen chiefly because of its ability to overcome high attenuation and noise level since all of these intercompany routes are relatively long, ranging from 120 to 220 miles through complex power networks.

Multitone Carrier Telemeter Channels

From the remaining points on the TVA's system, two or more telemetering readings were required to be transmitted. On all of these routes, carrier line traps and coupling capacitors were available for adding a second frequency by double-tuning the existing line traps and making additions to the line-tuning equipment. Such an installation is shown in Figure 4. These channels were provided by amplitude-modulated carrier equipment with a transmitter power output of 25 watts,[4] using audio tones ranging from 485 to 3,000 cycles per second for individual readings as tabulated in Figure 2. Figures 5 and 10, cabinets 1, 2, and 4, show typical carrier installations of this type.

In one case it was found that the line noise level was high, which interfered with the telemeter service. Over this 120-mile route, unity deviation ratio frequency-modulated carrier equipment[5] having a transmitter power output also of 25 watts was substituted for the original amplitude-modulated equipment, and more satisfactory results were secured. The average length of the eight amplitude-modulated channels is 100 miles.

Figure 2 shows how two of these multitone carrier channels utilize two receivers each, in one case to furnish Wheeler hydroelectric plant, an intermediate generating plant, with telemeter signals simultaneously with the end terminal at Wilson hydroelectric plant, and in the other case, two receivers are used to provide two transfer trip signals required for the protective relay scheme at an intermediate substation, Summer Shade, while the balance of six tones is received at South Nashville, the end substation, for telemeter service.

Figure 2 lists seven plant and company generation readings, six of which are telemetered over multitone carrier channels on a time-duration impulse basis, while the seventh, Chickamauga hydroelectric plant load, is telemetered over a pair of wires in a telephone cable.

Table 1 lists the circuit mileage established by each kind and quantity of equipment for the complete telemeter system totaling 5,688 miles in length, 97 per cent of which is established by carrier channels.

The three vertical rows of tie-line telemeter receiver-recorders on the left side of Figure 6 show the arrangement of instruments on the north wall of the load dispatchers' office at Chattanooga, Tenn. Plant and company generation receiver-recorders are in the right-hand end row.

Power-Line Carrier Frequencies

All carrier telemeter channels are transmitted over the power circuits with the exception of two originating at North Bristol and Nolichucky substations which are routed over open-wire telephone lines as indicated in Figure 2.

The problem of choice of carrier frequencies to use over the power lines was complicated by two factors: (1) many of the carrier telemeter transmitters were located at the edges of the TVA's territory immediately adjacent to or in switchyards owned by others who were using power-line carrier frequencies; (2) the large number of power-line carrier pilot relay[6] and telephone[7] channels in service on all of the TVA's circuits over which the new telemetering frequencies would have to be routed. It was desirable to minimize the changing of operating frequencies, not only because of the cost, but also because of shortage of labor during the War and the difficulty of taking transmission lines out of service to re-tune the line traps.

Based on engineering studies and carrier transmission tests, a carefully worked out frequency allocation plan was made. Thirty-one new frequencies were interspersed with those in operation requiring no changes in existing frequencies. This work involved close co-ordination with neighboring power companies. Nine of these frequencies are modulated by two to eight audio tones, and 22 frequencies are used for the 11 frequency-shift channels. Five carrier frequency-shift receivers are owned by others and are located at Magella substation, Birmingham, Ala.;[3] and at Woodward substation, Pine Bluff, Ark.

Frequencies used by the nine tone-modulated carrier telemeter channels range from 44 to 140 kc. Typical transmitting and receiving equipment of this design is shown in Figures 5 and 10, cabinets 1, 2, and 4. In general, the pilot relay carrier frequencies are located above the frequency band used for telemetering. The communication channels, ranging from 47 to 145 kc, are interspaced with each other and the balance of the services, including the 11 frequency-shift carrier channels, ranging from 37.5 to 131 kc, which are inter-allocated in the narrow interstices.

The frequency-shift equipment is of the crystal-controlled narrow-band type shifting only a total of 24 cycles per second at 37.5 kc and 101.5 cycles per second at 131 kc.

The eight frequencies used for the four frequency-shift telemeter channels within the TVA system are located in the band of 123 to 133 kc which has been reserved for frequency-shift telemetering.

The entire power-line carrier system in operation and under construction in the Tennessee Valley region is in excess of 300 terminals at 70 different points. A total of 160 frequencies is used, ranging from 37.5 to 195 kc.

Carrier Coupling and Trapping

Most TVA power-line carrier telemeter channels are coupled to the "B" (middle) phase wire to ground, which also is the carrier pilot relay channel path. One exception to this arrangement was the two transmission lines between Louisville, Ky.,[8] and South Nashville, Tenn., via Summer Shade where, because of the importance and length of these lines, it was desired to place the pilot relay and telemeter channels on separate phase wires. The carrier pilot relay channel was coupled between phase "B" of each line and ground. Because the continuity of the telemeter readings and transfer trip signals between these points is very important, phase "C" of each line was equipped with coupling capacitors, tuning units, and carrier line traps to establish duplicate circuits. One line is used normally and the other is available for an alternate path. The carrier terminal equipment is switched manually from one circuit to another upon telephone instructions via 2-frequency power-line carrier telephone channels, which are coupled "A" phase to ground on each line. This switching arrangement is shown schematically in Figure 2 at Paddy's Run (Louisville, Ky.), Summer Shade and South Nashville substations.

The phase wires to which all telemeter channels are coupled are trapped at both the transmitting and receiving ends as well as any intermediate by-pass points. This gives maximum stability to the carrier channels, permits most efficient use of the carrier signal, and blocks out noise

Figure 2. Main elements of carrier equipment and telemeter instruments used to establish 6,500-mile telemeter and load-frequency control systems

Only power and telephone circuits to which these carrier channels are connected are shown (For complete power system see Figure 1)

This terminal is used jointly for telemeter and protective relay purposes on the Pineville transmission line

Figure 5. (right) Multitone amplitude-modulated power-line carrier telemeter receiver and transmitter installed on racks at South Nashville substation

Carrier receiver for channel from Louisville, Ky., at left, and carrier transmitter for channel to Wheeler and Wilson hydroelectric generating plants (via Columbia primary substation) on right

from adjacent power circuits. Carrier traps also aid in confining the carrier frequencies to their local paths, thus reducing interference to other frequencies.

Telephone-Line Carrier Channels

Two recently established power interchange points are at North Bristol, Va., and Nolichucky, Tenn. The TVA owns and operates open-wire telephone circuits between these two points and Norris hydroelectric generating plant, over a portion of which is superimposed a group of three carrier-telephone channels. In this case, it was found more economical to use standard telegraph carrier channels for telemetering over the telephone circuits.[9]

This amplitude-modulated telegraph carrier equipment operates above the voice-frequencies on the physical telephone circuit but below the band of six frequencies used in the carrier telephone system. The telegraph transmitter has a power output of 0.004 watt and the frequencies employed are 4.53

Figure 4. Two-frequency carrier line traps in vertical position, coupling capacitors equipped with potential devices (front view), and carrier-frequency connections between capacitors and carrier line-tuning units (rear view) in typical TVA 161-kv switchyard

Telemeter and pilot relay channels are coupled to the middle phase wire to ground; two telephone channels are coupled to outside phase wires

Figure 6. Telemeter receiver-recorders on north wall of TVA load dispatching office, Chattanooga, Tenn.

Figure 7. Method of coupling load-frequency control carrier channels to each section of "A" phase of 161-kv busses in Chickamauga hydroelectric generating plant switchyard

Carrier line-tuning unit is in cabinet below coupling capacitor potential device assembly (rear view)

and 4.77 kc. Because this telephone line is made up of three individual circuits, the carrier-telemeter frequencies are bypassed at two intermediate points by standard high-and-low-pass filters. This arrangement permits the use of the three individual physical circuits for unrestricted telephone service.

The TVA's open-wire telephone circuits in East Tennessee also serve Watauga hydroelectric generating plant, which is now under construction. It is feasible to make the North Bristol and Nolichucky tie-line readings available at Watauga by making minor changes and adding carrier and telemeter receivers. However, when this is done, transmission studies indicate that a carrier repeater will be required between Nolichucky and Norris in order to maintain proper received signal strength at Norris.

The TVA's experience with telephone-line carrier for speech transmission, plus duplex telegraph, simultaneously, for printer telegraph service between Chattanooga and Wilson dispatching offices, has been satisfactory. This speech-plus-duplex equipment includes filters for removing from the speech path all frequencies above 2,200 cycles per second. The band between 2,200 and 2,700 cycles per second is employed for transmitting two carrier telegraph channels, on a frequency-modulated basis, at approximately 2,375 and 2,575 cycles per second. Such speech-plus-duplex equipment can be used for transmitting telemeter impulses.

Figure 8. Front view of power-line carrier frequency-shift master control number 2 transmitter (crystal-controlled) at Chickamauga hydroelectric plant, having a 24-cycle-per-second shift between high and low frequencies

Plans to install a direct telephone-line carrier channel for telephone service from Chattanooga to Watauga hydroelectric generating plant include the speech-plus-duplex feature for transmitting the number 2 master load-frequency control signal to Watauga, a distance of about 250 miles. The standard speech-plus-duplex equipment provides transmission of impulses in both directions simultaneously. Thus kilowatt indications of the generation of Watauga hydroelectric plant may be sent back to the load dispatching office at Chattanooga upon the addition of the telemeter instruments proper.

Table I. Telemeter and Load-Frequency Control Statistics, 1948

Kind of Apparatus	Quantity	Channel Mileage
Telemeter:		
Jointly-used power line carrier pilot relay sets	10	306
Power-line carrier frequency-shift transmitters	9	1,191
Power-line carrier frequency-shift receivers	9	
Power-line carrier audio-tone A.M. transmitters	8	3,291
Power-line carrier audio-tone A.M. receivers	10	
Power-line carrier audio-tone F.M. transmitter	1	480
Power-line carrier audio-tone F.M. receiver	1	
Telephone-line carrier transmitters	2	266
Telephone-line carrier receivers	2	
Telephone cable circuits	10	154
Telemeter instruments	63

Load-Frequency Control Channels

The master load-frequency control carrier channels, by addition of a carrier lead-in bushing and cable, made use of existing coupling capacitors that were in place to obtain potential in the hydroelectric generating plant switchyards constructed by the TVA and which are connected to phase "A" of each section of the main and transfer busses as shown in Figure 7. Exceptions made for reasons of economy are at Wilson where the control channels were coupled to existing capacitors on both Wheeler lines and at Fontana where both control receivers were connected to the line capacitor also used for establishing a carrier telephone channel.

Figure 10. Multitone amplitude-modulated power-line carrier telemeter equipment: receivers in cabinets 1 and 4, transmitter in cabinet 2

Frequency-shift carrier receiver for automatic load-frequency control in cabinet 3 at Watts Bar hydroelectric generating plant

Figure 11. Totalizing telemeter recorders and telemeter transmitters on south wall of load dispatching office, Chattanooga, Tenn.

Frequency recorders shown at bottom of center row and top of right row

The frequencies for the two master control channels are spaced 300 cycles apart, and the total shift of each pair of frequencies is 24 cycles per second. These two signals are sent out to the regulating plants over the three 161-kv circuits radiating from Chickamauga hydroelectric generating plant.

The first master control channel, placed in service in 1944, was not crystal controlled and it had a total shift of 600 cycles per second. The addition of crystals to this equipment at the time the second master control channel was installed permitted the narrowing of the channel to a shift of only 24 cycles per second, and operating the two pairs of frequencies much closer together than would otherwise be possible with the attendant saving in use of the carrier frequency band.

At Summer Shade substation, it was necessary to by-pass the number 1 control channel from the 161-kv system to a 66-kv line, as shown in Figure 2.

Continuity of the control channels is maintained uninterrupted under different switching conditions by the use of alternate parallel carrier paths. To date, no trouble has been experienced with the load-frequency control carrier receivers due to multiple-path transmission of carrier frequencies.

The two master control frequency-shift carrier transmitters at Chickamauga hydroelectric generating plant make use of a common 25-watt amplifier, line-tuning units and coupling capacitors. The front and back views of one of these crystal-controlled transmitters, rated at 2 watts output, are shown in Figures 8 and 9, respectively. A frequency-shift carrier receiver for load-frequency control purposes is shown in cabinet 3, Figure 10.

Table I lists the quantities of carrier and telemeter equipment required to construct these two control circuits totaling 840 miles in length, 97 per cent of which is established by carrier channels.

The seven regulating hydroelectric generating plants served by the number 1 master load-frequency control channel consist of 33 generating units with an installed capacity of 939,700 kw. The number 2 master load-frequency control channel serves six hydroelectric plants having 16 units with an installed capacity of 586,800 kw and, in addition, serves the Aluminum Company of America in such a fashion that they can re-transmit the signal to two of their hydro plants with an installed capacity of 197,500 kw in seven units.

From Figure 2, it will be noted that Chickamauga, Fontana, and Watts Bar hydroelectric plants with an installed capacity of 366,000 kws in ten units have access to both load-frequency control channels. This is to allow flexibility to meet varying operating requirements.

Figure 11 shows the location of the master load-frequency control telemeter transmitters in the dispatching office at Chattanooga, Tenn., together with other totalizing telemeter recorders and two system frequency recorders. Master control transmitter number 1 is in the left-hand vertical row and the master control transmitter number 2 is in the right-hand vertical row. The recorder used for totalizing purposes in the center vertical row is equipped with an impulse transmitter, and this instrument can be used when either one or the other of two master transmitters is out of service.

Power system frequency in the Chattanooga-Chickamauga area is shown on frequency recorder number 1. The frequency at Norris hydroelectric generating plant is shown on frequency recorder number 2. The Norris frequency is telemetered to Chattanooga via Watts Bar over two power-line carrier telemeter channels in series as shown in Figure 2. Figure 10, cabinets 2 and 4, shows the intermediate carrier terminal equipment used for this service along with several other readings which are transferred from one carrier channel to another. System frequency is used to bias tie-line loading in regulating generation.

The majority of the telemeter transmitters, proper, which actuate the carrier equipment are of the time-duration type and incorporate the Micromax principle of operation. The legend of Figure 2 shows the details of each telemeter transmitter and receiver which is mounted on the main switchboard panels of the substations and hydroelectric generating plants, and in load dispatching offices. Each telemeter receiver is arranged to give an alarm upon failure to receive a carrier signal or upon reception of a continuous carrier signal.

The six switches required for totalizing and choosing control channels are shown in the center of Figure 6, located between the two twin rows of receiver-recorders. A very flexible system of test blocks in the

millivolt circuits and the impulse circuits, external to the telemeter instruments, is available at Chattanooga for making special or emergency setups as well as to expedite maintenance work.

Four tie-line readings in the eastern part of the TVA's system are not only routed through Norris hydroelectric generating plant but are made available by telemeter-receivers which, by means of a selective switch, permit the use of any one or more of these readings for automatic load-frequency control when needed. This arrangement permits maximum flexibility to meet a variety of operating conditions which arise.

The generation of Wilson hydroelectric plant is telemetered to the Chattanooga load dispatching office via Watts Bar. Switches are provided at Watts Bar as shown in Figure 2 to permit using the reading sent from Wilson with a proportional load controller which allows the Wilson and Watts Bar hydroelectric plants to operate in parallel and carry a definite proportion of the regulating load.[10] This proportional control arrangement was completed in 1946.

All of the carrier equipment for telemeter and load-frequency control service is located indoors with one exception in the eastern portion of the territory where a frequency-shift telemeter transmitter is located outdoors in a switchyard. Temperature-controlled crystals are used in this carrier transmitter. Crystals used in indoor carrier apparatus are not temperature controlled.

Each telemeter and load-control circuit is connected to standard telephone twin jacks so that by means of standard telephone patch cords these channels can be routed over alternate paths in emergencies or for special operating setups. Carrier pilot relay channels which are normally used jointly for telemeter and relay purposes, as well as many that are not regularly so used, have been likewise connected to telephone twin jacks permitting the use of these channels in either direction.

The carrier pilot relay sets operate from 125- or 250-volt d-c control batteries, but the balance of the carrier terminals operate from 115-volt a-c station service. At all points where a-c operated telemeter and load-control carrier sets are in service, automatically-operated emergency power supplies are available which have assisted in securing a high degree of continuity of service from the carrier channels.[6]

Summary

The co-operation among members of the interconnected power systems in the southeast region in making joint carrier tests and studies and taking part in intercompany engineering discussions on the assignment of power-line carrier frequencies has been an invaluable aid in designing channels without the use of special carrier equipment.

Careful planning and engineering, giving due weight to economies and future growth, are necessary to make joint use of common power-line carrier equipment by two operating systems, especially if both parties already are using carrier channels.

The use of carrier line traps has allowed the establishment of a far greater number of carrier channels than would otherwise be possible. The use of these traps, low transmitter power, and judicious choice, spacing, and location of frequencies have kept intercompany interference to a minimum. When the few intercompany frequency conflicts have arisen, prompt corrective measures have always been taken on a co-operative basis.

A study of Figure 2 will show that the several different types of standardized carrier equipments available lend themselves to a large number of arrangements and combinations which provide a high degree of flexibility and operating reliability to insure maximum efficiency in generating power.

Discussion

C. W. Boadway (The Hydro Electric Power Commission of Ontario, Toronto, Canada): The over-all description of the telemetering and load control facilities used by the TVA was quite complete. It was shown how particular problems with an amplitude modulated multitone system were overcome by the use of multitone frequency modulation and frequency shift. This may prove valuable to present installers of this equipment.

It might be interesting for the author to explain the type of transmission used for relay signals, and further to emphasize the use of protection for power lines between the relay carrier current terminals. We assume that relaying in itself is a complete system in addition to the telemetering network described.

The author has clearly defined various installed uses for telemetering and load control as provided by power line carrier, telephone line carrier, open-wire physical circuits, and lead-covered telephone cables.

E. W. Kenefake (General Electric Company, Syracuse, N. Y.): It is certainly interesting to note the diversity of types of carrier-current equipment used on the TVA system for telemetering channels. It is indicative of the variety of application requirements which face a system communication engineer. The paper also leaves the very definite impression that the system has been well engineered and a credit to the people responsible for the planning. To others, it is certainly an excellent proving ground for various types of telemetering channels, which contributes valuable information as to the proper channel to use for given set of conditions. This is interesting to the manufacturer as well as the user. Perhaps the author will discuss the application advantages of various types of channels in a subsequent paper.

It is worthy to note that the TVA have converted amplitude-modulated tone equipment to frequency-modulation for reasons that arose in a particular application. As far as I know, that is the first time frequency modulation has been used for the transmission of multitone telemetering channels. Here is a case where the user has pioneered in the use of one of the various types of modulation for telemetering channels.

It is also evident that considerable planning and engineering have gone into the allocation of frequencies on the system, I am sure the techniques developed in this

case would be useful to the industry in general. I would like to encourage the author or one of his associates to prepare a paper on their method of allocation of carrier frequencies for some subsequent technical meeting.

T. De Witt Talmage: C. W. Boadway inquires about the co-ordination of the pilot relay carrier channels and telemeter service. He is correct in his assumption that the pilot relay carrier system is separate from the telemeter carrier system, with the exception of ten pilot relay terminals which are used jointly for both services. The pilot relay system, initially described in a previous paper,[1] has been more than doubled in size since that date. Ten per cent of the pilot relay carrier terminals now in operation are used normally for dual purposes, the continuous-wave carrier transmitters being keyed by telemeter auxiliary relays. Most of the carrier line traps originally installed for pilot relay service have since been double-tuned to block a second frequency which is used to establish a separate telemeter channel.

E. W. Kenefake emphasizes that certain phases of carrier application problems are of current interest to the industry and justify future discussion, namely, the method of allocating power-line carrier frequencies, and the application advantages of various types of channels. The subject paper describes the resulting pattern of using different kinds of channels and shows that a wide variety of channels can be co-ordinated for one particular type of service. The availability of carrier frequencies was, of course, an important consideration. As more experience is secured, the record can be enlarged accordingly.

Feeder Voltage Regulator Application on Power Systems

J. N. GOSINSKI
ASSOCIATE AIEE

J. R. OBERHOLTZER
ASSOCIATE AIEE

Synopsis: Feeder voltage regulators when properly applied will permit the optimum in economical design of power supply systems. The system designer must recognize definite relationships between the available range of regulators and the required voltage variations imposed by voltage drops in the subtransmission system, substation transformers, distribution feeders, and distribution system beyond the feedpoint. Since the effective range of regulators is reduced by inaccuracies in their control equipment, it appears justifiable to specify regulators with a total error of ± 1 per cent.

THE economical design of power transmission and distribution systems requires the proper allocation of voltage drops between the point of supply and the ultimate customer's service entrance. The judicious application of distribution voltage regulators is a normal requirement in the design of the usual type of power systems. They assist in obtaining optimum loading of the subtransmission and distribution systems and the furnishing of adequate customer service voltage. The use of distribution voltage regulators is particularly associated with systems where voltage variation and voltage drops determine the capability of the circuits. This paper describes the application of distribution voltage regulators under such conditions and their functions as related to other elements of system design.

Utilization Voltages

First, consider what values of voltage are desirable for customers' utilization. The joint Edison Electric Institute-National Electrical Manufacturers Association committee on preferred voltages has been studying this matter for a number of years and is issuing a report Preferred Voltage Ratings for A-C Systems and Equipment* which contains recommended voltage limits. Table I from this committee's November 1946 report[1] is reproduced herein in part as Table I for ready reference.

The "favorable zone" (125-110 volts) defined in the report is intended to include the majority of the utilization voltages in customers' premises. Quoting from the report, "Equipment will ordinarily be designed and rated so as to give fully adequate and efficient operation throughout this zone (although not necessarily with guaranteed characteristics at all voltages)." A reasonable maximum value for the drop in interior wiring is given in the Appendix of the EEI-NEMA report as three volts. Thus, a customer's service voltage range equivalent to the favorable zone listed above may be taken as 125-113 volts.

Electrical distribution systems should be designed and are normally operated in such a manner that service entrance voltage variations will be within limits which will provide proper utilization voltages at the customer's equipment. Designers of equipment recognize that voltage variations will exist and make provision for them in the operating characteristics of the equipment. The suggested values which have been set up by the EEI-NEMA committees, after exhaustive investigation of the practices of operating companies and manufacturing organizations, represent the optimum in balancing economical distribution design with economical utilization equipment design so as to provide the customer with satisfactory operation at minimum over-all cost.

Function of Distribution Voltage Regulators

The function of distribution voltage regulators on power systems is to compensate for voltage variations and voltage drops in the subtransmission system, the substation transformers, and the distribution system, so that the customer's service voltage may be held within acceptable limits.

On the usual subtransmission system the voltage at full load often will be lower than that at light load and the voltage drop through substation transformers will be greater at full load than at light load. These variations must be counteracted by the distribution voltage regulator. Of course, it is possible to design a power supply system such that there are no voltage variations which add to the duty of the regulator (zero regulation), and even such that variations are deliberately produced which will compensate for the substation transformer drop and provide the required distribution circuit primary voltage variations for proper customer service voltages as outlined below. In such a case, regulators may not be required. However, other considerations than exact control of the distribution voltage usually determine the subtransmission voltage variations.

Obviously it is not economical to design distribution circuits without voltage drop. With the use of distribution regulators, the design drop on an overhead urban

* Scheduled for printing in the spring of 1949.

Paper 48-263, recommended by the AIEE transformer committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted August 23, 1948; made available for printing September 17, 1948.

J. N. Gosinski and J. R. Oberholtzer are both with the Commonwealth and Southern Corporation, Jackson, Mich.

distribution system from the primary at the first customers' transformer (feed point) to the customer entrance on the most distant service from the last transformer may be as much as 9 per cent or 11 volts on the 120-volt base and still stay within established voltage limits. Experience and the result of studies in economic distribution system design have indicated definite desirable apportionment of the voltage drop beyond the feed point among the various individual components, that is, primary, transformer, secondary, and service as follows (120-volt base):

Primary circuits, first to last transformer	3 volts
Distribution transformer	$3^1/_2$ volts
Secondary	$3^1/_2$ volts
Service	1 volt

The optimum service entrance voltage of 120 volts can be obtained by a contact-making voltmeter (CMV) setting of 120 volts and a compensator setting of the full load voltage drop to the feed point plus five volts. Then the regulator will provide a full load voltage at the feed point of about 125 volts and a light load voltage of 120 volts plus the ratio of light load to full load multiplied by five volts. At full load the regulated feeder voltage at the substation will be higher than the voltage at the feed point by the amount of the feeder drop. The same will be true at light load.

Figure 1. Urban distribution voltage levels with various load conditions

(A) voltage at full circuit load
(B) voltage at light circuit load
(C) mode voltage at full circuit load

Figure 1 shows the various extremes of voltage which may appear on a typical properly regulated distribution system from the feed point to the last customer. Light load was assumed to be 25 per cent of full load for this diagram. For full circuit load conditions, the maximum service voltage of the first customer and the minimum service voltage at the last customer are shown to be 124 volts and 114 volts respectively, a maximum spread of 10 volts. The voltages which will result under light load conditions for these same locations are also shown. It is apparent that both the full load and the light load voltages at these locations are within the favorable zone. The extension of regulator compensation beyond the feed point gives particular advantages in maintaining the majority of customers' voltages within narrow limits from full load to light load. Because regulated design primary voltages are greatest at full load when transformer-secondary drops are generally greatest and conversely are lowest at light load when transformer-secondary drops are least, the net service voltage variation is held to a minimum.

Also shown on Figure 1 are the mode voltages at these locations under full load conditions. These mode voltages are the values which will occur during the greatest percentage of the full load period and will be an important factor in the life and over-all satisfactory performance of equipment. The full load mode voltage at the service entrance for the closest customer normally will be about 122 volts and for the most distant customer about 118 volts. Allowing 1.5 volts for the average interior wiring drop, the utilization voltage modes will then be 120.5 and 116.5 volts respectively for the customers at the

(Y) designates wye-connected.

* Except for the first line, which indicates the usual single-phase 3-wire systems, the figures in the second column refer to 3-phase systems. Single values designate systems on which single-phase equipment is ordinarily connected from phase to phase; double values designate systems on which single-phase equipment is ordinarily connected from phase to neutral.

** Since utilization at this level is confined principally to 6,600-volt motors in large steel mills, mines, and so forth, a nominal designation of 6,900 volts is commonly used and is included herewith, even though it is not consistent with other nominal voltages in the utilization group. The voltage zones for this level are likewise related to 6,900 volts rather than the 7,200 volts.

*** Equipment to be used on both the 120/208Y and the 240-volt systems must recognize the minimum voltage of the former and the maximum voltage of the latter.

† 14,400 includes many systems which have been called 13,800, and the voltage zones are correspondingly lower.

‡ Equipment designed for the Favorable Zone will in general give fairly satisfactory operation throughout the Tolerable Zone, except that modification of loading or alternate designs may be required for certain types of equipment.

Figure 2. Light load and full load voltage profiles

extreme locations on the system. Since the greater number of customers are located between the feed point and the end of the secondary system, the prevailing full load mode utilization voltage will be about 118 volts.

Thus the required range of the voltage regulator will be determined by three components: the requirements for correction of the variation in subtransmission system voltages and substation transformer voltage drops: the requirements for compensation of the voltage drop in the distribution feeder; and the regulation required beyond the feed point. If both a long and a short distribution feeder are supplied from the same substation, the minimum unregulated bus voltage which can be corrected by a regulator of a given per cent range will be determined by the full load requirements of the long feeder and the maximum light load unregulated bus voltage by the light load requirement of the short feeder. As shown on Figure 2, with normal distribution circuit design, the use of a ±10 per cent feeder regulator permits positive regulation on the high voltage supply of about 10 per cent. This permissible regulation makes it possible to save plant investments in subtransmission supplies for many substations.

Table II. Allowable Subtransmission Supply Variation ±10 Per Cent Regulators

(120 Volt Base)

Feeder drop, volts	0	4	8	0 and 4	4 and 8	0 and 8
Allowable subtransmission supply variation, volts	18	15	13	14	12	10

Table II shows the allowable high voltage supply variation with a ±10 per cent regulator for various combinations of feeder voltage drops. Full load substation transformer drop was taken as 4.5 per cent and light load was assumed to be 25 per cent of full load.

Table III indicates the regulator range which will be required for various combinations of power supply voltage regulation and distribution feeder drops. This illustrates the beneficial effects, in reducing the regulator range required, which are introduced by a negative regulation on the supply side of the substation.

The kilovolt-ampere capacity of the regulator usually is determined by the capability of the distribution circuit. Grouping of circuits for a single large regulator often is feasible when the load shapes are identical, such as commercial loads. Because the load factors may be 30 to 50 per cent, it may be satisfactory for the regulator to operate from 120 to 140 per cent of name plate rating during peak periods. Single-phase regulators are normally used on substations to supply radial distribution circuits when phase unbalance must be considered. Three-phase regulators are preferable because of their lower costs per kilovolt-ampere on systems on which a phase balance can be maintained, such as commercial circuits and primary networks.

Accuracy of Regulator Control

The actual voltage which the customer receives is determined entirely by the accuracy of control by the voltage regulator. Only recently has regulator accuracy been given the consideration which it deserves. While less accurate regulators may be lower in price it has been found that one per cent regulator accuracy is entirely justifiable on the basis of the improved results.

The control equipment for feeder voltage regulators consists essentially of a voltage responsive relay and a source of potential or "control voltage" which is applied to the terminals of this relay and which indicates the voltage at the regulator output terminals. The control voltage causes the relay to operate in response to variations in the terminal voltage such that this voltage or the voltage at some other specified point in the system is maintained within certain limits. A device called a "line drop compensator" simulates the voltage drop throughout a portion of the circuit being regulated and this voltage is introduced in series with the regulator voltage applied to the control element. The regulator is thereby enabled to maintain the desired voltages at points remote from the point of installation. The small inherent difference between values of control voltage applied to the relay which cause the "raise" and "lower" contacts to operate is known as the relay band width.

The effectiveness of the entire regulator is directly dependent on the accuracy of the operation of the control devices. Performance of voltage regulators which cannot be exactly predicted due to inaccuracies of their control devices may require excessive system investments to maintain satisfactory utilization voltages throughout the system. Errors in the control device will limit the availability of the full range of the regulator. For example, if the total accumulative error in the control equipment is ±2.5 volts and the relay band width is ±1 volt, the total error will be about 7 volts and the regulator may be considered to be only about 70 per cent effective. Of course, this assumes that all of the errors are accumula-

Table III. Regulator Range Requirements

(120 Volt Base)

Distribution feeder drop, volts	0						4						8					
Regulation on supply side of distribution substation, volts	−4	0	4	8	12		−4	0	4	8	12		−4	0	4	8	12	
Regulator voltage range required*	3**	7	11	15	19		6	10	14	18	22		9	13	17	21	25	
Regulator range required, per cent	0	±5	±5	±7½	±10		±5	±5	±7½	±7½	±10		±5	±7½	±7½	±10	±10	

* These figures include 3.7 regulator volts required for the distribution system beyond the feed point and 3.3 regulator volts required for the distribution substation transformers.

** This range is borderline. If the distribution substation transformer drop is small, no regulators are required. However, high transformer drop or some allowance for additional distribution circuit drop would indicate the use of ±5 per cent regulators.

tive and occur at the same time, and that the errors operate to limit the buck as well as the boost operation of the regulator. Some idea of the probable cost of additional system strengthening which may be required when designing for this degree of error can be obtained from analysis of the investment in transformer-secondary combinations on residential circuits designed for different voltage drop limits. The additional cost of the design for one volt less drop is in the order of $3.00 per kilovolt-ampere of diversified circuit demand for 4,160-volt circuits and in the order of $4.00 or more per kilovolt-ampere for 7,200-volt circuits. It must be realized that ordinarily there are about 10 volts which can be expended in the form of voltage drop in the design of a distribution circuit. Then each volt which is lost due to inadequate regulator performance will represent one volt out of ten in the measurement of increased investment required. It seems that an over-all improvement in the economics of distribution may reasonably be effected by investing more money in regulators of improved performance characteristics and thereby afford a greater saving in the distribution circuit itself. It appears that a limitation of errors to a total of about one per cent in the control equipment of a regulator is entirely justified by the additional useful range which will be realized.

Conclusions

The opinions expressed in this paper are based on experience with several power systems supplying an aggregate total peak demand of approximately 2,000,000 kilowatt-hours/hour on which system investment has been minimized by the use of feeder voltage regulators.

The most economical over-all power system design will result when the limitations on customer voltage variation are met by the use of feeder voltage regulators of specified accuracy. Distribution system designs have been evolved which make full use of this accuracy of voltage control.

Discussion

W. E. Birchard (General Electric Company, Pittsfield, Mass.): Gosinski and Oberholtzer have presented a factual appraisal of the application of feeder voltage regulators to typical power systems. Their evaluation of savings in investment amounting to $5,000 to $10,000 per feeder for each per cent improvement in regulator accuracy is very impressive compared to the small additional cost for high-accuracy regulators. This phase of distribution economics should be of interest to many distribution engineers.

Power System Voltage Control Without Feeder Voltage Regulators

N. N. SMELOFF
ASSOCIATE AIEE

ONE of the most important phases of power system planning and operation is the provision of required voltages for the various loads throughout the system to insure successful use of electricity and to promote its use for additional applications. However, provision of better voltage than necessary is not economically sound since voltage is a rough indication of the ratio between system capability and the size of the load.

Thus the broad problem is to provide enough capacity for adequate voltage control at the minimum over-all cost. At the same time, of course, the facilities provided must fit into the broad patterns for development of the system through the years.

It is the general practice of Pennsylvania Power and Light Company to provide adequate voltage to its customers without the use of feeder voltage regulators. This paper presents the reasons for this and the methods used.

Voltage Requirements

Before proceeding with a description of the control methods used by the company, a short discussion is required to explain what is meant by "adequate" voltage. It is obvious that a customer's equipment will not operate properly with, say 80 per cent nominal voltage applied to it. Lights will be dim, heaters will work slowly, and motors may not start. On the other hand, 120 per cent nominal voltage will result in reduced life of equipment. Thus it is necessary that the voltage supplied to the customer be at the right level to operate his equipment properly.

The second condition for adequate voltage is that the changes must not be such as to have a detrimental effect upon the operation of utilization equipment. An occasional voltage fluctuation of several per cent is not objectionable, but a repetitive voltage fluctuation of even $1^1/_2$ per cent causes annoying flickering of lights if the frequency is right. On the other hand, a slow change in voltage, even relatively large, may not be noticed.

Pennsylvania Power and Light Company System

A brief description of the company's system and territory is necessary to make clear the reasons why feeder voltage regulators are not generally used for voltage control. The area served is about 9,300 square miles in the center of eastern Pennsylvania with a widely dispersed population of about $1^3/_4$ million. (See Figure 1.) Out of the 774 communities with populations over 100 served by the company, only eight are larger than 20,000 and the largest is only about 100,000. The peak load is over 600,000 kw and the annual energy consumption is over $2^3/_4$ billion kilowatt-hours. Customers are served from any line of the four standard system voltages of 66 kv, 12 kv, 4 kv or 120/208 volts if the capacity available is adequate. Choice of voltage is based only upon the size of the load and the availability of suitable lines. No loads are tapped directly from the 220-kv lines which are used exclusively for the transmission of bulk power.

The power supply system, shown in Figure 2, consists of a 66-kv network of lines, fed at strategic points from large generating stations and a 220-kv transmission system. While there is some local distribution from generator busses, the bulk of the power is delivered directly to the 66-kv system, from which transformation is made for supply directly to large power customers as well as to the standard distribution voltages of 12 kv and 4 kv.

The significant feature of the system from the voltage control standpoint, is that customers are served from any of the standard voltages except the 220 kv. This practice results in an unusually large number of 66-kv substations as is illustrated in Figure 2.

Few if any systems, as a general practice, provide voltage regulators for any unit smaller than a feeder. In fact, many systems provide only bus voltage regulators and adjust the feeder lengths and loads to give adequate voltage on all feeders from a single bus.

The company's 66-kv system is in an analogous situation, in that the customers are too numerous for each to be supplied economically with a separate regulator. Instead, the idea of bus regulation is extended, and the entire 66-kv system treated as a sort of bus whose voltage is raised and lowered to fit the load, by using the reactive capacity of generators and of synchronous condensers installed at the load centers and load ratio control at the points of step-down from 220 kv. Since the condensers are required to provide the system reactive capacity, the voltage regulation feature is obtained at little extra cost.

Controlling the transmission system voltage level to suit the load is not an unusual idea, since many companies raise the general voltage level throughout the transmission system as the load increases.

It is the extent to which the practice is followed by this company that is distinctive and requires careful system planning and day-to-day operation.

Paper 48-264, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted August 3, 1948; made available for printing September 10, 1948.

N. N. Smeloff is system planning engineer with the Pennsylvania Power and Light Company, Allentown, Pa.

Figure 1. Territory served by Pennsylvania Power and Light Company

Operating Procedure

In practice, the system voltages are controlled by establishing definite voltage schedules based on time for each point where a means of control is available, such as a generator, a synchronous condenser, or load ratio control from the 220 kv. Account is taken in the schedules for the normal variation in system (or area) load from day to day as well as from hour to hour. This company's load has a pronounced morning peak.

A typical schedule for voltage at a control point is shown in Table I. The transition from one voltage to another is made slowly. The operator follows this schedule, within the limits of the equipment under his control, without any further instructions from the central control authority. If the voltage gets beyond the ability of the local equipment to control it, assistance may be obtained from adjacent areas. The voltage schedules have been established and adjusted as experience dictates to give adequate voltage to the customers.

At the present time, there are 32 manually-operated control points, of which 19 are generating stations. In addition to the generators there are at various points around the system slightly more than 125,000 kva of synchronous condensers or other synchronous equipment. It is planned to reduce the manual control points to 22 by 1951 by relocation of facilities, conversion to automatic operation, dispersal into automatically-controlled installations of switched capacitors, and shutting-down of older generating stations.

That such a method of voltage control is quite feasible is borne out by the fact that a system peak load of well over 700,000 kva was carried with less than 60,000 kva of this being served through feeder voltage regulators. Within the next few years it is planned to eliminate half the feeder voltage regulator capacity at locations where the present facilities are of inadequate capacity and must be strengthened. Those to be left are required because of special circumstances as will be discussed later.

In Figure 3 are shown the general types of voltage curves which are obtained at supply points on a normal weekday. Analysis of the voltages of 111 major points of supply on the system shows 29 per cent type A, 37 per cent type B, 30 per cent type C, 4 per cent type D, and no type E curves. Present plans call for elimination of the type D which are not satisfactory for a supply point. Some of the type C curves will be improved on feeders which are so long or heavily loaded that the voltages at the far end are type E due to line drop. Others will be allowed to remain type C until the load growth requires corrective measures.

At the present time, an extensive program of installation of 90,000 kva of switched capacitors well dispersed around the system is under way. These capacitors are to be used for two purposes, voltage control, and release of transmission and distribution capacity. By controlling each capacitor bank with a voltage-measuring relay combined with a weekly time clock, which changes the calibration of the voltmeter to provide higher voltages during peak load periods, aid is given to the system voltage control plan. Capacitors, switched on-and-off by a voltage relay, reduce the on-peak drop and allow more load to be carried without exceeding the allowable voltage variation or spread.

In establishing the new Sunbury generating station, where an initial installation of 150,000 kw is planned for service early in 1949, it was necessary to be sure that the generator would provide the voltage variation required and still maintain stability. The plant will be required to operate at full kilowatt load and with very small reactive loads at off-peak-hour voltage levels. These requirements were met at no additional cost.

10 p.m.–12 p.m.	100	100	100	100

Historical Example

A good illustration of the principles and methods used for controlling voltage without feeder regulators, is afforded by the history of development of a property acquired by the company in 1930. In a region covering nearly 1,200 square miles having a 60-cycle load of 23,000 kw, the only source of power at that time was a single 42,500 kva, 66–12 kv step-down substation approximately in the center. The power was carried away from the substation by a 12-kv subtransmission system with the lines running radially. No customers were served directly from the 66 kv and only in the immediate vicinity of the 66—12 kv substation were there any 12-kv customers. All the other power was distributed at 4,600, 4,000, or 2,300 volts obtained by step-down stations from the 12 kv and controlled by feeder voltage regulators. The 12 kv was unsuitable for serving residential loads or even noncritical industrial loads because of its excessive voltage variation. At some places, variations as high as 17 per cent were obtained and 12 per cent was common. With such voltage drops the losses, both power and reactive, were excessively high.

Shortly after the acquisition of the property, an over-all regional development plan was formulated. This provided for establishing a 66-kv loop with ties to existing and planned generating stations and the main system. Step-down supply points from the 66-kv to the 12-kv system would be set up to serve the areas as required. The 66- and 12-kv lines were to serve all customers except in the built-up areas for general distribution to smaller loads where a 4,000-volt system would be used in conformity with the system standards.

To provide immediate relief before these long-range plans could be realized, two 12-kv switching centers were established at strategic points remote from the original supply center, suitable for later use as 66—12 kv supply centers and where 12-kv lines could be brought together easily. At each of these centers fully automatic 5,000 kva synchronous condensers were installed. This immediately provided additional carrying capacity on the 12-kv circuits by taking advantage of load diversity and improved power factor. The resulting improvement in area 12-kv voltage variation also made it possible to supply industrial, residential, and rural customers directly from this voltage.

Shortly thereafter the 66-kv loop was started and 66—12 kv supply centers provided as and where necessary to unload the 12-kv lines. Load growth in the region was cared for by converting the 4,600-volt lines to 12 kv and shortening the distances served at 4,600 volts. Gradually the 4,600-volt voltage regulators were removed from places where they were no longer needed and used in other locations which still needed their help.

This program was delayed by the war but is now proceeding rapidly. Eventually it is planned that the 4,600-volt lines and regulators will be removed almost entirely and the feeder voltages controlled by the 66-kv system variation supplemented as needed by local switched capacitors and synchronous condensers.

The condition of this property at the time of purchase illustrates in an exaggerated manner a major disadvantage of regulators. The voltage supplied to the 4,600-volt customers was adequate for utilization yet the 12 kv had been allowed to deteriorate until it was unusable to supply loads directly. Thus, even the larger customers had to be served through 12-4.6 kv transformers and regulators. Any load growth meant establishing new substations and 4,600-volt feeders.

Situations Requiring Regulators

There are certain situations, as was mentioned previously, where a feeder voltage regulator is the most economical and satisfactory solution. Several of these occur on this system and are of general interest.

Such a situation is that of a load tapped from a relatively weak circuit such as an interconnection which is used for the transmission of power in varying amounts in either direction depending upon system generation requirements. Under these conditions the supply voltage is apt to vary over a considerable range and not in accordance with the local voltage requirements. The lowest supply voltage may well occur at the heavy load periods

Figure 3. General types of voltage curves at supply points on week days

of the area. The solution for such a situation is most easily provided by a feeder or bus voltage regulator.

A similar problem is posed by a small load fed directly from a generating station low-tension bus. Where the generating station has a high-side voltage schedule to follow, the low-side variation may be too great for the load. To avoid "letting the tail wag the dog" by limiting the generator bus voltage variation to suit the local load at the expense of the main system requirements, a regulator is installed.

Summary

Plans for the future development of the company call for a continuation of operation without regulators as a general practice. By co-ordinated development of the system as a whole, it will be possible to avoid the use of regulators, except as temporary crutches for a few weak spots. Installation of switched capacitors to control voltage on feeders or busses helps not only the local feeders or busses, but also the higher voltage systems supplying them. The cumulative effect of many individual installations is quite appreciable.

As a contrast the feeder voltage regulator controls only the voltage beyond its location and adds its reactive burden to the system supplying it.

Discussion

H. C. George (The Detroit Edison Company, Detroit, Mich.): The Detroit Edison Company like the Pennsylvania Power and Light Company has found it possible to eliminate some line regulators as a result of improvements in power house voltage regulation. There is a difference, however, in the extent to which regulators have been removed and also a difference in the method of varying the power house voltage. Our practice can be described rather briefly.

First, we believe that as a load building proposition it is advisable to maintain good voltage for residential customers. Many appliances are much more satisfactory with close regulation. This has no doubt been a factor in building up our range load to 26 per cent saturation. The quality of service is closely watched in regard to the amount of flicker existing and also to the voltage spread. In the Detroit district only a 7-volt spread in voltage is allowed at the lighting customer's meter while outside of the Detroit district a 10-volt spread is allowed.

These lighting customers and small power customers are served from 4,800-volt distribution circuits some of which have voltage regulators and the rest of which are fed from regulated busses. At one time each circuit was individually regulated. During those years when new equipment was hard to obtain, it was found possible to remove many line regulators by grouping similar circuits together on each of two or more regulated busses. By careful grouping of lines the usual quality of service was maintained for customers.

Lines serving the larger power customers at 24,000 volts and 4,800 volts are not, in general, equipped with voltage regulators. Many 4,800-volt power lines had regulators at one time but after improvements had been made in system regulation at the power houses, most of the power line regulators were removed and used on new distribution circuits.

Our method of power house voltage control accomplishes the same result as the Pennsylvania Power and Light Company's method but in a different manner. We have four steam plants, two in Detroit, one about 60 miles up stream and the other less than 20 miles down river. Nearly all of our generators have manual voltage control, although some are being equipped for automatic regulation. The voltage at the two city plants will run from 118 to 126 volts, while the voltage at the more distant plants will run from about 116 to 132 volts.

At the two Detroit plants the voltage is adjusted to maintain a definite voltage on a compensated voltmeter. At each of these two plants the current for compensation is obtained from the current transformers on the three or four lines feeding one substation. The substation selected in each case has a load cycle which corresponds quite closely in shape to the system load cycle. Thus by an indirect means, the voltage on the transmission system in the city is made to gradually rise and fall in accord with the changes in system load. The amount of compensation used is such that the voltage on most of the city substation 4,800-volt busses remains fairly constant, that is, sufficiently constant for most power customers without the use of substation voltage regulators.

The two out-of-town plants are controlled in a somewhat different manner. The voltage at these plants is adjusted as required to maintain satisfactory voltage at 24-kv and 40-kv stations and substations around the system. Maximum and minimum limits have been established for four 120-kv-24-kv stepdown stations. In general, there is a 4-volt difference between the maximum and minimum limits. One set of limits is given for so called "heavy load periods" and a lower set for "light load periods."

Synchronous condensers and static capacitors spread around the system give additional help in regulating system voltage. Of the synchronous condensers, we have 11 running from 1,500-kva to 30,000-kva, mostly equipped for automatic regulation. Thirty-one substations have installations of static capacitors which are controlled from time switches.

C. J. Lake (General Electric Company, Schenectady, N. Y.): Controlling the transmission system voltage level to suit the load is not an unusual idea, but the extent of this is limited and if the effective voltage spread is not sufficiently narrow, adequate voltage for all customers will not be available. Therefore, the success of voltage control on a system without regulators depends upon the voltage spread. The more money invested into the system for copper, capacitors, or synchronous condensers, the more the annual carrying charge will be. In return, there will be a saving due to reduced I^2R losses.

The use of capacitors and synchronous condensers to control the reactive power and power factor is basically and economically sound. Maximum efficiency in transmission will be obtained when the power factor is unity and no reactive power flows around the system. A company can afford to approach this criterion in many cases. Hence, any system which cannot maintain adequate voltage limits throughout the entire system after the criterion has been reached must either use regulators or rebuild the lines. An economic study of each particular feeder is the most logical method to assure that the proper choice is made. Naturally, an accurate prediction of the future conditions and changes is never attainable but the better the prediction, the better will be the conclusions of an economic study.

The investment required to change over from manually operated control points to automatic operation is another item that must be considered. Regulators automatically maintain the voltage of electric circuits within predetermined limits and their prices include the control equipment for automatic operation. In other words, some of the money invested in regulators buys automatic control for the system.

As loads grow, there will be a time reached when the voltage spread will have to be reduced even after the maximum permissible amount of reactive power corrective equipment is installed. It may be, very likely at that time, more preferable to use regulators than to rebuild the lines. Another factor vital for the success of system voltage control is the pattern of the daily load curve of every load area in the system. The diversity in the load curves for all parts of this system is very small. In some systems, this cannot be realized due to variety of customer load requirements.

The reactive burden of regulators has many times been improperly interpreted. Actually, the average reactive power needed by regulators in ordinary systems amounts to about 2 per cent of the total inductive reactive power of the load connected to them. The probable error in varmeter readings is about 1 per cent, which is customarily considered insignificant, and it is reasonable to assume that the reactive power needed by regulators is negligible. The increase in system voltages during peak loads usually increases the system inductive reactive power more than this due to the saturation effects in transformers and motors. That is, a 5 per cent increase in the system voltage increases the system inductive reactive power about 10 per cent.

S. B. Farnham (General Electric Company, Schenectady, N. Y.): As electric system loads continue to grow, the economic necessity for full utilization of the existing system tends increasingly to dictate a more uniform voltage level from generating station to point of supply to the load area. This follows from two fundamental considerations. First, the limitation in the loading of such equipment as generators and transformers is generally a thermal one. Hence, if this equipment is to be utilized to the fullest extent for its primary purpose of generating or transforming kilowatts, it must be relieved from carrying kilovars. By generating the kilovars close to the loads where they are needed, as with synchronous condensers or static capacitors, this end is achieved, and at the same time the improved power factor results in reduced voltage drop and consequently a more uniform voltage level from generator to load. Second, the permissible loading of overhead transmission and distribution lines is generally limited by voltage drop. In most cases, the major portion of the drop is that resulting from transmitting kilovars. Again, therefore, by generating these kilovars as closely as possible to the load, the line loading limit is increased and the system voltage gradient reduced.

Smeloff's paper is a timely illustration of a practical evaluation of this situation at the transmission and subtransmission level. He may justifiably take credit for realizing significant gains in uniformity of system voltage levels, while at the same time permitting increased utilization of the kilowatt-carrying ability of his system.

As his projected plan for increasing use of automatically switched capacitors develops, it would be of interest to know what changes, if any, are anticipated in the voltage schedules maintained at generating stations.

W. E. Birchard (General Electric Company, Pittsfield, Mass.): The Pennsylvania Power and Light Company system seems somewhat unusual in that it has many large customers supplied at 66 kv. Presumably, these customers have their own distribution systems, and it would be interesting to learn what spread in utilization voltages they experience. They can, of course, re-regulate the voltage on portions of their systems just as many power companies do.

Another question may be of concern to operating engineers. What restrictions does this method of operation impose on interconnection with other power systems?

Smeloff has stated that his objective is to provide adequate voltage control at minimum over-all cost. But has he thoroughly investigated the relative costs of various combinations of generator control, synchronous condensers, capacitors, and feeder voltage regulators? Eliminating the cost of feeder voltage regulators may have resulted in greater expenditures for lines and other apparatus. Studies of other systems have shown that each item has its proper function, and that feeder voltage regulators, far from being "temporary crutches" or luxuries, are providing the lowest cost means of voltage control when applied in the combination most suitable for that system. There are many additional situations where it is impractical to maintain balanced loading of phases, and balanced loading and length of feeders, and in those cases feeder voltage regulators are a virtual necessity. Regulators are very flexible in that they can be relocated easily to suit the changing requirements imposed by growing and shifting loads.

Smeloff substantiates his conclusions by the statement that 700,000 kva was supplied with only 60,000 kva served through feeder regulators. Are not the following the two real criteria?

1. What were the extremes of utilization voltages actually supplied? (not the schedules of substation voltages that operators were striving to maintain by manual control.)

2. How did system investment and operating costs compare with corresponding costs for a system design utilizing the best combination of feeder voltage regulators with other apparatus such as generator control, synchronous condensers, and capacitors?

D. K. Blake (General Electric Company, Schenectady, N. Y.): We may differ among ourselves as to what voltage spread constitutes good voltage. We do not differ, however, as to where the point of good voltage must be and that point is the consumer.

Smeloff's paper presents a practice that is understandable and agreeable up to the subtransmission supply of distribution substations. But, from the distribution substation bus to the first transformer and the effect the method described by Smeloff has on the allowable drop from the first transformer to the last transformer is not clear. Does Smeloff mean that he regulates the 4-kv bus of each distribution substation with synchronous condensers or switched capacitors, as is commonly done when tapchangers or regulators control the bus voltage to a group of feeders? If he does mean this, then does he locate distribution substations so that the voltage difference from the transformer nearest the substation bus to the transformer farthest from the substation bus regardless of which feeders they may be on, is the same as he would otherwise have on a feeder with individual regulators if they were used. If so, then the point to be cleared up is, how is it possible to do this economically on a system-wide basis, in spite of wide differences in load density and unavoidable long branches?

The higher the load density, the shorter the feeders become and hence it becomes more practical and economical to use group or bus regulation because the difference in length between the bus and first transformer becomes smaller. At the lighter densities, distances become greater, and hence the need for individual feeder regulators in some locations or smaller bus regulated substations in other locations where subtransmission supply is available at reasonable cost. Over and over again, company after company has found supplementary regulation in the form of branch regulators very economical. In fact, supplementary branch regulators make bus regulation practical in many instances.

As far as my experience goes, there is a proper place in the industry for all of the regulating methods. It is quite common to find large systems making use of all of them. Bus regulation, feeder regulation, and branch regulation, have an economic place in distribution systems in addition to capacitor switching, synchronous condensers and generator fields at transmission and subtransmission levels.

The most fundamental of all distribution system regulating problems is the drop between the first and last transformer which determines the most economical feeder size and as a result of this the most economical substation size.

N. N. Smeloff: There are a few additional advantages that capacitors have over voltage regulators which should be mentioned. Voltage regulators raise the voltage along an entire feeder by the same percentage, which results in the first customer placing a top limit on the amount of load which can be carried on a feeder. The use of automatically switched capacitors at the ends of the feeders, on the other hand, raises the voltage level at the end by a greater percentage than at the substation, allowing the maximum load carried to be increased to a higher value, perhaps to the thermal limit of the conductor in some cases. To answer the question raised by Blake, the capacitors for this purpose are normally located some distance out along the feeder and not at the supply point bus.

In general, the use of feeder voltage regulators results in the deterioration of the voltage of the supply system, such as the subtransmission, to the point where it cannot be used to serve even industrial customers directly without additional regulators. In the long run, this tends to produce a situation where all power used passes through regulators with a resulting increase in system investment.

We are pleased to hear from George that the Detroit Edison Company has found it possible to eliminate some line regulators by using powerhouse voltage control instead, because it confirms the results of our studies and practices. We agree that it is desirable to maintain good voltages for residential customers, and our standards for service to this class of customer are about the same as those described by George. For industrial customers, we allow a somewhat larger variation.

Using Lake's figures for the reactive burden of regulators, the additional load to be supplied by the Pennsylvania Power and Light Company would be approximately 15,000 reactive kilovolt-amperes. While this is not an extreme amount, it is a load which we do not have at present.

The increase in system load with increased powerhouse voltage is present whether or not regulators are used, so long as the system voltage is increased during peak load periods.

In answer to Farnham's question, it is not anticipated that there will be any major changes in the voltage schedules of the generating stations as automatically switched capacitors are added to the system, because they are added only to compensate for increased drop between the generating station busses and the loads.

Judging by the first paragraph of Birchard's discussion, the paper does not make clear enough the relation between the voltages supplied to the customers and their needs. It is our practice to furnish voltages adequate for general distribution to residential and commercial loads over relatively long distances compared to any encountered by individual customers. To the best of our knowledge, no customer regulates the voltage supplied him except for very special types of loads requiring an exceedingly fine degree of control such as laboratories. In this case a small regulator is used on only that small portion of the load requiring the close control.

There are practically no restrictions imposed upon interconnections with other companies, because most utilities raise and lower their voltages in a manner similar to the Pennsylvania Power and Light Company. As was pointed out in the paper, the method is not uncommon; it is only the extent to which it is carried that is not customary.

With regard to the economic question raised by Birchard, studies made in the past indicated that for a far-flung network such as the Pennsylvania Power and Light Company, with customers and generating plants at so many locations, it is cheaper to limit the supply point voltage variations so that regulators are not needed. We agree that the engineering required for application of this method is more difficult, but an economical solution can usually be obtained.

With regard to the criteria for the adequacy of voltages supplied without feeder regulators:

1. The number of voltage complaints received from customers is not excessive.

2. There is a trend in many companies for the elimination of feeder voltage regulators at the present time, particularly for high-density areas.

3. The number of kilovolt-amperes supplied without passing through regulators is offered only as supporting data that such a method is indeed feasible.

Planning the Development of a Metropolitan Electric System

M. L. WARING
MEMBER AIEE

THE Consolidated Edison System supplies electricity to an area of 535 square miles including the major portions of the city of New York and of Westchester county which joins the northern boundary of the city. This large metropolitan area contains a population of over 8,500,000 people with a load density varying from a maximum of 220,000 kw per square mile in the highly concentrated areas, to a minimum of only about 100 kw per square mile in the suburban areas.

The electric load consists mainly of services to small customers, of whom about 2,500,000 are supplied directly, with possibly another 400,000 served indirectly. Aside from the supply to railroads and rapid transit lines, large industrial loads represent less than four per cent of the total load. It is probable that two-thirds of the peak demand is used for lighting purposes. Estimates have been made which indicate that New York city contains the largest concentration of small business in the country with some 230,000 concerns, each employing less than seven workers on the average. The effect of these factors has been to decrease the fluctuations in load caused by business cycles as compared with other systems having a larger proportion of heavy industrial load.

During the past 20 years, the peak load supplied to the area has more than doubled. Served at the beginning of this period by a number of individual operating companies, the system is now completely integrated and operates all major power stations in the area with the exception of three plants owned and operated by the Board of Transportation of the city of New York. The integration of facilities together with a large increase in load have resulted in major changes to the system. The development of the system during these 20 years has been accomplished as a gradual process guided by the following general fundamental policies which were formulated early in the period and have been adhered to up to the present time:

1. To maintain a margin of reserve or spare capacity determined by the probability method and designed to provide a minimum but adequate degree of reliability.

2. To expand and modernize existing low-pressure generating stations by the installation of topping turbines and associated high-pressure boilers.

3. To reinforce the tie feeder system interconnecting generating stations when required to minimize the over-all system reserve capacity, but to install topping turbines, wherever practicable, as the first means for providing additional capacity needed by local areas or parts of the system.

4. To segregate the secondary network system into isolated areas each fed independently from a single switch gallery and limited in size to a load that can be reenergized in the event of a shut down.

It is the purpose of this paper to review these policies and to summarize their effect on the design of the system.

Determination of Generating Capacity Requirements

Shown in Figure 1 are curves illustrating the relation between the system net generating capacity and 1-hour peak loads for each of the years from 1920 to date. Due to the integration of a number of individual operating companies and the effect of the depression, ample reserve capacity was available for a number of years. However, the abnormally high rate of growth of the post war load has made it important to determine accurately the amount of reserve generating capacity required for contingencies and for overhaul. The system contingency reserve requirements have been determined by means of the probability method, using for this purpose the following basic information.

Unit Forced Outage Rate. This factor represents the per cent of the operating time that any unit of equipment may be expected to be forced out of service due to contingency. Based on national average data modified to reflect the Edison System experience, the following rates were used: high pressure boilers, 3 per cent; low pressure boilers, $2^1/_2$ per cent; high pressure turbines, 3 per cent; low pressure turbines, $1^1/_2$ per cent.

Variation of Daily Maximum Capacity Requirements for Load and Overhaul. In a calendar year there are 253 days excluding Saturdays, Sundays, and holidays which must be considered in an analysis of the probability of forced outages in excess of available reserve. The rapid growth of summer load in recent years has steadily narrowed the margin of capacity available to schedule the outage of equipment for overhaul during the off-peak months. Since this trend is expected to continue, it is necessary to plan on the assumption that the capacity needed during the summer months to meet the peak-hour load plus scheduled overhaul requirements will be substantially the same as the capacity required to supply the winter peak-hour load. However, there is a variation in peak load from day to day due to weather conditions. During the summer months this variation (excluding short thunderstorm peaks) exceeds 200,000 kw, and in the winter it amounts to about 100,000 kw. The daily variation appreciably decreases the exposure to forced outages in excess of available reserve. A correction factor of 90 per cent was introduced, therefore,

Paper 48-266, recommended by the AIEE system engineering committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted July 21, 1948; made available for printing September 10, 1948.

M. L. WARING is a planning engineer in the system engineering department of the Consolidated Edison Company of New York, Inc., New York, N. Y.

Figure 1 (left). Comparison of net generating capacity with net maximum one-hour load for Consolidated Edison System

Figure 2. Years of operation per day of loss of load as a function of reserve in megawatts

into the calculations, this being representative for the system. This correction factor is the ratio of the average requirements for load and overhaul to the peak requirements.

Type of Contingencies. The probability method used to determine reserve requirements considers unit outages as random events obeying the binomial law of probability. The method does not take into consideration protection against major catastrophies which might involve the outage of an entire station. Furthermore, the calculations are limited to the outages of turbines and boilers alone. With the major tie reinforcements now authorized and under construction, the studies indicate very definitely that system reserves can be made available to any portion of the system in adequate amounts, and that the only value needed for planning purposes is the reserve requirement for the entire system.

The Edison System is interconnected with adjoining power systems. Such interconnections decrease the amount of reserve capacity required as compared to that needed if each system were to operate independently, inasmuch as it is unlikely that adjoining systems will be subjected to extreme contingencies simultaneously. Although no accurate determination has been made, approximate studies indicate that the Edison System, in an emergency, could rely on at least 80,000 kw of reserve capacity from its interconnections if adjoining systems maintain reserves computed in a similar manner.

Various means of reducing load are available which do not inconvenience consumers too seriously. Chief among these is voltage reduction which, if limited to about 5 per cent, will produce a like reduction in load without undue hardship. In the case of the Edison System, it is practicable to reduce load to the extent of 150,000 kw in the winter and 100,000 kw in the summer on very short notice.

Summarized in Figure 2 are the results of reserve calculations for the system as it exists today and as it will exist as of 1952 after completion of the various units now under construction.

The determination of the desirable reserve capacity to be maintained is a matter of judgment in which it is necessary to balance the cost of capacity additions against the degree of reliability desired. Present plans are based on maintaining a minimum installed generating reserve capacity of 350,000 kw, which when added to the 80,000 kw of interconnection capacity would provide a total reserve of 430,000 kw. This will provide a spare capacity of 16 per cent of the 1952 peak hour load. Capacity outages in excess of this amount can be expected to occur on the Edison System approximately one day in eight years. Should such excessive contingencies develop it will then be possible to resort to voltage reduction, and it may be seen from the curves in Figure 2 that it would not be necessary to exceed a load reduction of 100,000 kw more frequently than one day in about 50 years. Because of the inherent stability of the Edison System, reasonably accurate forecasts of load can be made for periods up to four or five years in advance and a close co-ordination between load

Figure 3. Schematic diagram of boiler and turbine equipment at Waterside Station after completion of present construction program in 1949

growth and new capacity installations can be maintained.

Expansion and Modernization of Existing Plants by the Installation of Topping Turbines

It is apparent from an inspection of Figure 1 that the cessation of load growth during the depression years made it unnecessary for a number of years to provide additional generating capacity to meet the total system load requirements. At that time the system generating plants operated at pressures ranging from 200 to 400 pounds per square inch gauge. The most efficient plant had a heat rate of approximately 15,000 Btu per kilowatt-hour while the 200 pounds per square inch gauge stations had heat rates of about 25,000 Btu per kilowatt-hour.

The Waterside station was then a 200 pound per square inch gauge plant containing a number of 25-cycle condensing turbine generators supplied by a large number of small boilers. The station is located strategically in Manhattan adjacent to the East River, directly opposite the heavily congested Grand Central and Times Square areas. Due to the rapid growth of the 60-cycle a-c system caused by the changeover of many consumers from d-c to a-c supply, it became imperative to increase greatly the 60-cycle supply to this midtown area.

Studies, which included the evaluation of relative operating expenses as well as annual carrying charges on capital costs, showed substantial savings in favor of providing the capacity required for the midtown Manhattan area by installing topping turbines at Waterside, rather than by transporting large blocks of power over additional tie lines from adjoining stations. A total of four 60-cycle topping turbines exhausting steam to the 200 pounds per square inch gauge header were installed prior to the war for this purpose. High-pressure and temperature boilers having an efficiency approaching 90 per cent replaced the older, low-pressure boilers which had an efficiency of only about 75 per cent. The efficiency of steam utilization in the existing low-pressure turbines remained unchanged, but the new topping units produced additional electric energy at a heat rate of about 4,500 Btu per kilowatt-hour.

Two additional topping units, associated boilers and two new 200 pounds per square inch gauge condensing turbine generators are now under construction at Waterside. A diagram of the station as it will exist after completion in 1949 is shown in Figure 3. There will be a combined generator rating of 658,200 kw, which is an increase of 80 per cent over the 1934 station capacity of 366,200 kw. Furthermore, the heat rate of the station will have been improved from some 25,000 Btu per kilowatt-hour to better than 11,000 Btu per kilowatt-hour. In this manner it was possible to more than double the over-all station efficiency and to decrease substantially the unit operating labor and maintenance expenses of the system.

In the case of the Waterside development, retention of the 200 pounds per square inch gauge steam header offered two unique advantages. The first of these is to permit the gradual conversion of the existing 25-cycle turbine generator units to 60 cycles, as progressive changeover from the d-c to the a-c supply system may develop. The second advantage is that it facilitates obtaining substantial production savings in the supply of steam to the district steam heating customers of the New York Steam Corporation. The uptown district of the Steam Corporation is supplied in part from the 200 pounds per square inch gauge header at Waterside. The exhaust steam from the topping turbines can be used, therefore, either for the production of electricity in the condensing turbine generators or to supplement the supply of steam to the district steam system. Because of diversity in time between the demands of the electric and steam systems and by pooling of reserve capacity requirements, substantial savings in capacity and production costs have been obtained. Sufficient feedwater treatment equipment has been provided to permit the supply of as much as 2,000,000 pounds per hour of steam to the district. This method of operation has proved itself to be practical and economical.

As shown in Figure 4, two topping turbines and boilers have been installed in the Sherman Creek station. All but two of the low-pressure machines were 60 cycle and these two have since been rebuilt from 25 to 60 cycle operation. The capacity of the station has been increased from 151,000 kw to 271,000 kw and the heat rate of the modernized portion of the station has been improved from about 24,000 to less than 12,000 Btu per kilowatt-hour. This development provided the capacity needed to meet the growth in load of the northern area served by the Edison System.

The third station to be modernized by the installation of a topping unit was the Hell Gate plant, located in the south portion of the Bronx on Long Island Sound. As one of the base load stations of the System, Hell Gate had been designed originally to accommodate the type of daily load cycle then prevalent. As a result, the boiler capacity was sufficient to supply the full load steam requirements of the turbine generators for a few hours over the peak load period of the day. However, because of a very marked increase in daily load factor, the boiler

Figure 4. Schematic diagram of boiler and turbine equipment at Sherman Creek Station

Figure 5. Schematic diagram of boiler and turbine equipment at Hell Gate Station

plant was no longer capable of supplying the sustained day load requirements caused by the change in load characteristic of the system. To correct this situation additional boiler capacity was required and it was found more economical to install the needed boiler capacity at higher pressures and temperatures with a topping turbine exhausting steam to the existing 265 pounds per square inch gauge steam header. Very little increase in peak hour station capacity was obtained since it was desirable to remove a 40,000-kw turbo-generator as well as two rows of boilers to provide room for the new installation. This development differs, therefore, from those at Waterside and Sherman Creek in that the primary purpose was to increase the sustained load capability of the plant. A diagram of the completed station is shown in Figure 5.

Plans are now being prepared to install a topping turbine at the Hudson Avenue plant for reasons very similar to those already explained for the Hell Gate station. This will be the tenth topping turbine to be added to the system and will bring the total capacity of such units to 556,000 kw. It will practically complete the Consolidated Edison's program of modernizing and expanding its low-pressure plants by the installation of topping turbines. All 200 pounds per square inch gauge boilers have been retired with the exception of approximately 200,000 kw of such capacity. This closely approximates the standby or peak load capacity required for the Edison System and it is unlikely that there will be economic justification for retiring additional 200 pounds per square inch gauge boilers in the near future. All other capacity installations contemplated or under construction at this time are of the full expansion type.

Interconnections Between Generating Stations and With Other Systems

The expansion of existing generating stations by the installation of topping units has been the most economical means for providing additional capacity required to accommodate load growth in local areas or parts of the system. Now that the topping program approaches completion it has become increasingly desirable to reinforce the tie feeder system. Accordingly, the installation of large capacity ties between generating stations is being accelerated.

Tie feeders between generating stations and between independent systems are installed, generally, for one or all of the following reasons:

1. To pool reserve capacity.
2. To permit interchange of energy for best over-all production economy.
3. To take advantage of diversity in time of area or system peak loads.
4. To provide transmission capacity to distribution substations located at load centers.

Figure 6. Generating station locations and tie feeder system in 1950

Shown in Figure 6 is a map of the Edison System after completion of work in progress giving the geographic location of the generating stations, the tie feeders interconnecting them, and the two interconnections with adjoining systems.

The interconnection with the Niagara Hudson System is a double circuit, 138,000-volt overhead transmission line extending from the Dunwoodie substation in Westchester County to the Pleasant Valley substation of the Niagara Hudson System located near Poughkeepsie. Placed in service in 1932 it has proved itself to be useful for most of the reasons given previously.

As explained in a preceding section, the benefits obtained from the pooling of spare or reserve generating capacity requirements through interconnections amount to a capacity saving on the Edison System of at least 80,000. A major share of this saving is obtained from the Niagara Hudson tie. In addition it has provided an outlet during high water periods for energy produced upstate by hydro stations at such times as there was an insufficient amount of load on the Niagara Hudson System to absorb such power. It has permitted the Niagara Hudson System to purchase energy produced in Edison's steam plants at times when the cost of production in steam plants on the Niagara Hudson System would have been higher and vice versa. The tie line has served as a means for transmitting power to a total of three stepdown distributing substations supplying the bulk of the electric load in Westchester county.

The second interconnection, placed in service recently, ties the Edison System with that of the Long Island Lighting Company. This tie contributes to the total savings in installed capacity requirements and will permit substantial reductions in production cost by permitting either company to purchase energy from the other whenever it is economical to do so. Unlike the Niagara Hudson System, there is a substantial diversity between the times of the electric system peak loads on the Edison and on the Long Island Lighting System. For example, in the summer months the Edison System reaches its peak hour load between 10 and 11 A.M., whereas the Long Island Lighting System reaches its peak in the evening from 8 to 9 P.M. This reduces the amount of capacity necessarily operated on the two systems, and so effects a reduction in operating cost. The Long Island Lighting tie at

present consists of a single circuit 138,000-volt underground cable. However, facilities have been provided to install a second circuit at some time in the future. The tie extends from the Jamaica substation to the Valley Stream substation of the Long Island Lighting Company.

Work is now in progress to extend the 138,000-volt tie line from the Jamaica substation to the Hell Gate generating station. Upon completion there will be a double circuit tie line from Hudson Avenue to Jamaica and from Jamaica to Hell Gate. Completion of this work will form a tie loop between Hell Gate and Hudson Avenue in parallel with the lower voltage ties running through Manhattan. These latter ties operate at either 27,000, 13,000, or 11,000 volts and tie the Waterside and East River stations into the loop between Hell Gate and Hudson Avenue. To provide adequate control of power for this extensive loop both phase angle and voltage control apparatus are being installed as shown in Figure 7.

The tie feeder additions described before are scheduled for completion in 1950, and at that time there will be sufficient tie capacity between the various generating stations on the system to permit a complete pooling of reserve capacity requirements for the individual portions of the Edison System. Meeting this criterion provides more than enough tie line capacity to make it possible to select and operate individual generating units in their most economical combination for any level of system load.

The 138,000-volt tie loop between Hudson Avenue and Hell Gate will also serve as transmission to the Jamaica and North Queens substations. These substations will reduce the voltage to 27,000 volts and will supply substantially all of the load distributed in the Borough of Queens.

Figure 7. 60-cycle system diagram in 1951 showing phase-angle and voltage control

The Transmission and Distribution System

A number of changes have been made in methods used to distribute electricity which have produced corresponding changes in the fundamental basis of the plan adopted for the Edison System. The supply to Manhattan was developed originally as a d-c distribution system and because of the requirement for uninterrupted service and the importance of its load the d-c network system continued to be developed until 1931. The northwest section of Brooklyn was also developed originally with a d-c system. As the electric art developed, a-c systems of distribution came into existence. The Boroughs of the Bronx, Brooklyn, and Queens were developed with a-c systems of distribution utilizing substations as distributing stations from which emanated 2-phase primary feeders supplying 3-wire single phase secondaries. With the continued development of new equipment and increased load requirements, Brooklyn, Queens, and the East Bronx changed their 2-phase primary distribution systems to 3-phase systems. The West Bronx because of its large 2-phase primary commitments continued to develop the 2-phase system. The generation and transmission of electricity to the d-c substations was 3-phase alternating current at 25 cycles when supplying the d-c secondary system and 60 cycles for a-c substations supplying the a-c secondary system. The development of the a-c network protector in 1926 caused a radical change in a-c distribution. This device made it possible to eliminate the need for a-c substations and to provide an a-c service with a reliability similar to that of the d-c system.

Increased operating experience and improvements in the a-c network unit, protector and transformer, have resulted in establishing the 3-phase 120/208 volt a-c secondary network system as the standard throughout the system territories. The company requires that new load be arranged for a-c service and, as a result, the a-c network gains in area and load density as the opportunity and necessity arise. In addition the a-c network is extended into radial districts whenever the load density and other conditions warrant.

In the lower load density areas, such as are found in the outlying sections of the city, the company still uses the radial system of a-c distribution which affords customers an entirely adequate service. The cost of this service in such areas is appreciably lower than that of an underground a-c network.

Figure 8. Supply to segregated 60-cycle network areas in 1950

Until 1936, the 3-phase a-c network system consisted of continuous 120/208 volt grids covering large geographical areas. The supply of each grid was through network transformers fed by high-tension feeders emanating from the several generating stations. As a result of trouble experienced with this type of system the following guiding principles were formulated, subsequently put into effect, and have been adhered to since:

1. A-c network secondary grids shall be subdivided into network areas, each area being completely segregated from all other network areas. The load in each area shall be small enough so that the area can be reenergized independently by the station which serves as its base supply.

2. Network feeders shall carry load to only one network area and shall not be bifurcated with feeders to other areas.

3. Each network area shall be fed from a single generating station.

4. The supply to each area shall be distributed among sufficient bus sections to permit the loss of any one major bus section.

The adoption of this type of network system resulted in a fundamental change in the plan of system development. Rather than intermesh high-tension feeders from all the generating stations as in the former manner where the stations were synchronized through common secondary grids. It is now the practice to interconnect the generating stations by a system of direct ties and to segregate the network load into blocks which are small by comparison with the capacity available on the generating station bus supplying them. In addition to simplifying the normal and emergency supply to distribution load, this method offers great flexibility in the planning of the expansion of the system. It is possible now to relieve any portion of the system needing load relief either by transferring load away from it to some other part of the system, or by reinforcing the direct tie feeders connecting it with the balance of the system.

Until very recently it has been the practice to install 13- or 27-kv distribution busses and switching equipment as an integral part of the generating station and distribute directly to the load from the station except in outlying areas such as Westchester county. The cost of such conventional switch gallery construction in New York city has reached a point where it is no longer economical to distribute directly from the generating stations. Estimates indicate that so long as present costs prevail, it is more economical to construct these switch galleries at a site where horizontal rather than vertical construction can be carried out. As a result, under present conditions, it is considerably less costly to install double transformation and construct the switching facilities at a location where the equipment can be spread horizontally even though the substation is located within a very short distance of the generating station. The first of these network area distributing stations is now under construction and will be located approximately two miles from the East River generating station. In the East River development it was found that due to space limitations it would be necessary to construct the gallery vertically if located at the station. Coupled with this condition was the fact that the system has grown to a point where circuit breaker duties have become a serious factor. Accordingly, a 69-kv bus will be erected at East River to which will be connected, through transformers, the generators and the incoming ties from the adjacent generation stations. 69-kv underground feeders will be fed from this bus and they will supply the network area distributing stations.

In Figure 8 are shown segregated network areas and the distributing busses from which they are supplied. Of particular interest are the supply to the City Hall network area from the East River station as described before and the supply to the North Queens and the Jamaica substations from the new 138,000-volt tie feeders between Hell Gate and Hudson Avenue. These three area substations represent recent and marked changes in the fundamental plan of the transmission system.

Discussion

C. N. Metcalf (Consolidated Edison Company of New York, Inc., New York, N. Y.): Waring has condensed an immense amount of detailed planning for the Consolidated Edison System over many years into this paper and he should be commended for the clarity of presentation.

It has been suggested that a brief discussion of the method of supplying the secondary network grids or areas in the Consolidated Edison System would be of interest in connection with this paper. As stated in the paper, "the secondary network grids are subdivided into areas—completely segregated."

Figure 1 of the discussion shows how each of the separate secondary network areas is supplied from segregated major bus sections divided physically by fire walls to prevent the spread of trouble. Six major bus sections are shown, a minimum of four sections has been established as basic design. Each of the major bus sections is subdivided into two minor sections by a circuit breaker and thus one-half of any major bus section may be restored in a relatively short time after failure.

Twelve distribution feeders are grouped in two feeder bands—1 and 2, 3 and 4, and so forth. The two feeders comprising each band are supplied from different major bus sections. Thus, in the event of failure of one of these major bus sections, both feeders

Figure 1 (left). Network supply plan

Figure 2. Master feeder plan

will not be out in any of the bands. The distribution feeder supply to the network grid is designed to cover simultaneous outage of any two feeders without serious contingency conditions.

A typical master feeder plan, with assignment of feeders to the six major bus sections, is shown in Figure 2 of the discussion. This indicates clearly how the distribution feeders are run in pairs or "two feeder" bands, physically separated from other feeder bands in the network grid and in routing to the network grid area.

The sizes of network areas, are important from a design standpoint. Each area must be small enough so that it can be energized independently. The maximum size is dependent on the number of feeders that can be closed simultaneously or in groups, in quick enough succession, so that network protector fuses will not be blown by short time overloads.

The maximum size of a network area is also dependent on the ability of the boiler plant and tie feeders to absorb the load imposed on re-energizing. Since blocks of load may be picked up in progressively larger amounts, the sizes of the areas may vary. For the Consolidated Edison System, the load of the areas varies from 40 to 75 megawatts where they are supplied by 13,000-volt distribution feeders and up to 150 megawatts where supplied by 27,000-volt feeders. These limits are not necessarily the maximum as this is reviewed as conditions require.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): This paper is of considerable value to the industry. I have a number of questions as follows:

1. Referring to Figure 1 and the discussion in the paper, are the data on "net generating capacity" based on the nameplate rating of the generators or on what?
2. In what manner is the possible error in load forecast covered? That is, is there an allowance made for such an error by adding to the initially forecast load or is the allowance intentionally covered by the magnitude of the reserve that is determined to be required?
3. In Figure 7, are the emergency winter ratings, for example, for the two 200 megawatt tie lines between Jamaica and North Queens based on both lines being in service at the same time and carrying such a load? (This question is asked because I think that both these lines are in the same trench.)
4. What is an outline of the method used to arrive at the figure of "at least 80,000 kw" as being the reserve capacity available from interconnections?

E. L. Michelson (Commonwealth Edison Company, Chicago, Ill.): Waring's paper is an excellent summary of the history of the Consolidated Edison System. Papers of this type are very helpful to other system planning engineers, since it aids in evaluating situations that occur on their own systems.

It may be of interest to point out some of the situations on the Chicago System that parallel the conditions outlined by Waring in his paper.

In Chicago it became necessary to establish heavy interconnections between generating stations approximately 20 years ago. The availability of water and other factors, did not permit the installation of capacity at the load centers, and, therefore, it was necessary to install generating capacity somewhat remote from the load and to transmit the power over 66-kv cables to the load centers.

The Consolidated Edison System has made extensive use of topping units to modernize their system, and to provide additional generating capacity. In Chicago this has been done to only a limited extent—two topping units of a total capacity of 80 megawatts having been installed in recent years.

In Chicago, as in New York, the use of the a-c network system has been adopted for power sypply to the downtown area to replace the d-c system. The principle of developing the network in small sections is being followed in Chicago in a manner similar to that described by Waring.

It was interesting to note that in New York the practice of distributing power at the generated voltage is being replaced by the use of 69-kv feeders. In Chicago this plan was developed a few years ago, and there are now several 69-kv substations under construction. These substations eliminate costly construction at the generating stations due to the need for high-capacity equipment at these locations, they eliminate the use of long 12-kv lines to substations, and they permit expansion of switching structures more nearly in proportion to the system load growth.

M. L. Waring: The author is indebted to the discussors for describing in greater detail some of the points covered briefly in the paper and for indicating the similarity of conditions that exist in different metropolitan areas.

Metcalf's description of the method of supplying completely segregated secondary network grids is interesting. This represents the most satisfactory solution that has been found to overcome the difficulties encountered when feeders from different generating stations were synchronized through common secondary grids of wide extent.

Halperin raised a number of pertinent questions to which the answers are as follows:

1. The "net generating capacity" of the production plants is their net peak or 1-hour capability after allowance for variations from the nameplate rating of the equipment as determined by operating experience. In some instances the plant capacity is limited by the capability of the boilers after an allowance for the normal outage of stoker-fired boilers as required for cleaning purposes.
2. No allowance for possible error in load forecast has been made. As stated in the paper, due to the inherent stability of the Edison System, reasonably accurate forecasts of load can be made for periods up to four or five years in advance.
3. The two 200,000-kw tie lines between Jamaica and North Queens will be installed in the same trench. The rating is for both lines in service. With only one line in service, its rating can be increased approximately 10 per cent.
4. The reserve capacity available from interconnections of "at least 80,000 kw" was determined by computing the Edison System proportionate share of the over-all savings or reduction in reserve capacity requirements obtained by pooling of reserves through interconnections. The computation involved, therefore, a determination of the reserves required by each company without interconnections and comparing this result with the lesser reserve required by the combined, interconnected systems.

Michelson makes an interesting comparison of situations on the Chicago system with those that parallel the New York conditions.

Of particular interest is that both systems are beginning to use 69,000-volt feeders from generating stations to area distributing stations for very similar reasons.

Emergency Control of System Loads

Introduction*

GENERAL interest in the effect of voltage and frequency reduction on load has increased with the continued reduction in reserve capacity in the last few years. There has been continued discussion of the variation in load with variation in voltage and frequency since the publication of our paper on System Load Swings in 1940,[8] which was presented under the sponsorship of the AIEE committee on power generation.

The difficulty which our industry has experienced in obtaining new generating equipment, together with the rapid increase in load, has contributed to reducing the margin of reserve capacity. Today, a contingency which otherwise would be minor may result in a serious emergency unless means are found to reduce load immediately. Careful study of the effects of variations in voltage and frequency will enable a sound choice of method for load reduction for such emergencies as well as add to our knowledge of the cause and control of load swings.

Surprisingly uniform agreement has been reached based on extensive tests and operating experience on the effect of voltage variations. It is generally agreed that a variation of 1 per cent in voltage results in power load variations of a little over 1 per cent and in reactive load of about $1^1/_2$ per cent. However, substantially no agreement has been reached on the effect of frequency variation.

The purpose of this section of this joint paper is to point out some of the possible effects of attempting to reduce load by dropping frequency and to indicate the need for tests on the particular system before sound conclusions can be reached.

* J. E. McCormack and J. M. Comly.

In broad general principle, a reduction in frequency is synonymous with slower operation of rotating equipment, and at slower speed less work is done. However, there are several factors that might alter this situation and make it unsafe to draw the obvious conclusion that system load may easily be dropped by simply reducing frequency.

In general, a reduction in voltage will reduce lighting and other resistance-type power loads but will have lesser effect on motor loads. It will decrease the system reactive load by reducing the exciting current of the transformers and other induction devices. On the other hand, a reduction in frequency will have little effect on lighting and other resistance loads but might be expected to reduce the power input to motors. As an indication of the wide variation in results to be expected from a reduction in frequency, we offer the results of tests on an individual refrigerator, two different types of common fluorescent fixtures with their lamps and a small distribution-type transformer. Figure 1 shows the variation in amperes, watts, power factor, and watthours per hour with variation in frequency on a popular make of domestic refrigerator when the supply voltage is held constant. The curves clearly show that watts decrease with decreasing frequency, but that amperes and watthours increase. Thus a domestic refrigerator at reduced frequency requires less watts to operate, but since it is required by its control to keep the refrigerator cool, it must do so by running longer and at a lower efficiency. If each of a larger group of refrigerators is in operation longer, the effect will be to increase the number of units in operation at any instant and decrease the diversity. Under such conditions, the coincident load for this and any similar automatic equipment will first decrease, then slowly increase to a load greater than at normal frequency. The reactive load will increase sharply as frequency is reduced and then gradually increase an additional amount as the watts increase.

Figure 2 gives some interesting results of similar tests on two different types of fluorescent lamp fixtures. In both cases, the reactive load increases with decreasing frequency. The single lamp fixture shows an increase of 51 per cent in watts for a 10 per cent decrease in frequency while the double lamp fixture shows no appreciable change in watts.

Tests were made on a 1-kva transformer at frequencies from minus 10 per cent to plus 10 per cent of rated frequency. There was no evidence of saturation. When feeding a constant 100 per cent power-factor load the input did not vary appreciably with frequency, but with a 70 per cent power-factor load the current and watts increased about 1 per cent with 10 per cent reduction in frequency.

Figures 3 and 4 are curves showing a significant part of the data included in our 1940 report of system load swings.[8] This report was concerned principally with the origin of cyclical swings in the load on our interconnected system but two tests were made with Hudson Avenue station separated from the system. Each were short time tests but are interesting in showing the difference in the effect of voltage and frequency variations on the load supplied from that station. Figure 3 shows the variation in station bus power and reactive load with voltage when the frequency is held constant. Figure 4 shows the variation in the power load when the

Paper 48-267, recommended by the AIEE system engineering committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted August 11, 1948; made available for printing September 9, 1948.

J. M. Comly and J. E. McCormack are both with the electrical engineering department of the Consolidated Edison Company of New York, Inc., New York, N. Y.; C. B. Kelley is power pool manager, The United Light and Railways Service Company, Des Moines, Iowa; H. W. Phillips is supervisor, Pennsylvania–New Jersey Interconnection, Philadelphia, Pa.; and T. W. Schroeder is electrical engineer with The United Light and Railways Service Company, Davenport, Iowa.

Figure 1. Effect of frequency on load—domestic electric refrigerator

voltage is held constant and the frequency is varied. During the time the voltage reduction test was made the approximate composition of the Hudson Avenue load was 68 per cent lighting and 32 per cent miscellaneous power load. During the time the frequency reduction test was made, the approximate composition of the load was 39 per cent lighting and 61 per cent miscellaneous power.

These estimates of load composition are neither accurate nor detailed enough to be useful except for comparison with similar estimates of load carried by other systems.

A possibility for error in judging the effect of frequency changes on load is the effect of frequency on the accuracy of the switchboard meters. The direct error for indicating instruments due to frequency change is probably small except in the case of induction-type instruments such as watthour meters, but an appreciable error may be caused indirectly by the fact that the burden, or load, on the potential and current transformers supplying the instruments is changed by the change in frequency. Although the changes are small in percentage, the load drop due to frequency alone is also small in percentage.

Figure 2. Effect of frequency on load—fluorescent lamps

All of the tests described previously, as well as our general discussion, point to the probability that variations in the composition of the load will materially effect the results obtained by voltage or frequency changes. As none of us have been able to obtain the composition of our system loads with any degree of accuracy, it appears necessary either to accumulate sufficient test data on which to base judgment or to adopt the simpler procedure of obtaining necessary load reduction by using voltage as the control. From past experience, it seems apparent that the control of load by voltage change provides a more definite and convenient method in most cases than such control by frequency change. Voltage is a parameter which can be changed in a local area comparatively easily without affecting an entire interconnected system while frequency is system wide, unchangeable in one local area without an immediate effect on the entire system. Voltage reduction reduces reactive load as well as kilowatt load, while frequency reduction may increase the reactive load at a time when reactive capacity is a limit as well as real power capacity.

Another, and perhaps a more important consideration in the effect of frequency reduction, is that most of our stations operate as a part of an interconnecting system which in turn is connected to other systems. Frequency is the one parameter common to all parts of the interconnecting systems so long as they remain connected. Any attempt to obtain load relief for one shortage area by frequency reduction requires a uniform adjustment of generator throttles throughout the interconnection so as not to affect seriously the loading of interconnecting tie lines. Certainly, it will create new problems on systems using automatic load-frequency control equipment.

Let us suppose that in a particular case, we may reduce the frequency without reaching a limit imposed by the operation of the interconnection. Any station auxiliaries, that are electrically driven, will slow down and may tend to reduce the station capacity at a time when maximum generation is required. The frequency reduction will be accompanied by a voltage reduction caused by the slowing down of the generators, accentuated in certain cases by the slowing down of direct connected or electrically-driven exciters which supply the generator fields. If the necessary adjustments are made to hold the station bus voltage to its scheduled values, there may be a tendency for the voltage at the load to rise due to the decrease in the inductive reactance of feeder reactors, feeders, mains, and services. With reduced reactance in these circuit elements, the voltage difference between the station bus and the service for a given load will be less than at normal frequency. At the same time, the reactive load on the bus may increase since the exciting current of all transformers and similar inductive devices will increase at the reduced frequency. For these reasons, the full effect of a change in frequency on the voltage at the customer's service point cannot be accurately judged by observation of station bus voltmeters.

Figure 3. Effect of voltage on system load

A further consideration for a large interconnection is one of revenue. When frequency reduction is made, the load will be reduced throughout the whole interconnected system. In most cases, the load relief required would be on a small part of the interconnected area, and there may be no need for load reduction on the remainder of the interconnection. In contrast to this, load relief by a reduction in voltage can be applied to the local shortage areas without creating a loss of revenue in the other areas.

The conclusions we draw from our study

Figure 4. Effect of frequency on system load

are that the effect of frequency variation on load is of academic interest and might provide many interesting hours of discussion, but voltage control as a practical operating tool to obtain temporary emergency load reduction is simpler and more flexible of application and the effects are definitely predictable. The limits of voltage reduction which may be used are determined by the voltage limits of customer's equipment. In general, 10 per cent below the rating of lamps, motors, and other customer's equipment, is permissible. In areas where the voltage is already low, the reduction cannot be as great. In any event, the stability of the system is not affected by the voltage reduction and the reactive component of the load is reduced as the voltage is reduced. Reduction in frequency may cause serious difficulties with reactive load and may reduce system capacity. Under special conditions, where motor loads constitute a large percentage of the total system load, a combination of voltage and frequency reduction may prove desirable.

The use of voltage or frequency reduction for load relief should not be considered as a permanent consideration for system planning, but should be used only as a means for meeting unusual temporary emergency conditions until a normal safe margin of reserve capacity can be restored. The authors of the other papers in this series are presenting results of extensive system load tests which will provide much needed practical data on the effect of voltage and frequency variations on these particular systems. Papers previously published on this general subject may be found in the Bibliography.

Voltage and Frequency Reduction as Tools for Handling Emergency Capacity Conditions*

The limited reserve in generating capacity that has existed over the past two years prompted the electric operating companies in the Pennsylvania–New Jersey Interconnection and the Baltimore–Washington Interconnection to make a thorough analysis of the several procedures which might be used over periods of short duration for the temporary curtailment of load. It was agreed that the most favorable plans for load curtailment would be those which caused the minimum over-all disturbance of the customers. Application of voltage and frequency reduction within limits will affect customers very minutely. However, the over-all reduction in load on a large system becomes sufficient to equal the output of the largest generator.

Several tests have been made in our area to determine the reduction in load which results from the lowering of voltage and these have indicated that a drop of 1 per cent in voltage will give an average reduction in load of 1 per cent. This has been verified by tests and actual experience on other systems.

We had previously found that by lowering frequency 1 per cent, the load would be reduced by 2.6 per cent. However, how much of this reduction was synchronous and asynchronous load and how much was resistance load was not known. Tests were conducted in December 1947 and January 1948 to provide additional information. Of the total load reduction of 2.6 per cent, 1.9 per cent results from reduction of synchronous and asynchronous load, while 0.7 per cent accrues from the dropping of resistance load.

On the basis of these extensive tests, we have been able to set up a definite procedure for utilizing these operating tools for load control during emergency conditions of short duration.

General

The limited reserve situation which developed during and since the war made it necessary to extend co-ordinated operation to the 17 interconnected operating companies in the Pennsylvania–New Jersey and Baltimore–Washington Interconnections. The geographical area in our co-ordinated operating group includes the entire state of New Jersey, the eastern half of Pennsylvania, the northern section of Delaware and the Baltimore-Washington area. The coincident peak load in this area in December 1947 was 5,100,000 kw. In addition to operating on a basis of maximum economy, the co-ordination was extended to conservation of scarce fuels, conservation of fuels in areas that were short and the scheduling of maintenance to assure a minimum outage of equipment with preference given to that equipment which was most badly in need of repair.

In spite of this co-ordinated operation, it became apparent that multiple forced outages might necessitate the curtailment of load. Other areas in the United States confronted with this same problem had investigated the possible load relief which might be obtained by lowering voltage. Voltage drop had also been used during the war in both England and on the continent to curtail load and, in addition, a drop of from 4 to 5 per cent had been made in frequency for the same purpose. We had made extensive studies of the effect of frequency variation prior to the war for purposes entirely independent of load control and during these studies found that a variation of 1 per cent in frequency would cause the load to vary about 2.6 per cent. We realized at that time that part of this drop accrued from voltage reduction on unregulated circuits. However, at that time we were not interested in where or why the load was reduced and made no further effort to analyze the results.

During the reserve deficiency which has existed during the past few years, many discussions have arisen among electric utility operating men as to just what could be accomplished through frequency reduction. Almost everybody agreed that the dropping of frequency would reduce load, but many maintained that the load reduction was caused primarily by the drop in voltage which accompanied the slowing down of generators. This, however, was not the opinion of the men from England and Europe who had been utilizing frequency drop to control load for an appreciable period.

The divergence of opinions on the subject indicated that we would be justified in conducting additional research on the effect of frequency reduction and, consequently, plans were made for making a special frequency drop test. There are 317 generators with a total capacity of 5,560,000 kw in our co-ordinated operating area. No automatic frequency devices are employed at any time since the tie line capacity is exceptionally high and the frequency is at all times under the control of the interconnection dispatcher. The combined area load is exceptionally steady on clear days between 1:30 p.m. and 2:15 p.m. and, therefore, this period was considered most acceptable for conducting a frequency drop test. The normal load during this period of the day was 4,500,000 kw.

Description of Procedure

In order to assure that no material change of load occurred during the test, it was decided to run the frequency high at approximately 60.25 cycles for a period of 15 minutes and then drop it about one-half cycle to approximately 59.75 cycles for another 15 minutes, and finally return to the high frequency for the last 15 minutes. In this way, the loads for the first and last periods could be checked one against the other and any material change

* H. W. Phillips.

Figure 5. Test number 2 voltage drop probability on unregulated circuits with 0.487 per cent frequency drop

determined. All companies were instructed to take 15 minute integrated readings on all generators and to read voltage every 5 minutes. It was planned to obtain voltage readings at representative locations on the system with an equal division between regulated and unregulated circuits.

The Conowingo Hydro Electric Station of the Philadelphia Electric Company which has a normal capacity of 252,000 kw was utilized to handle the major portion of the frequency control, although other hydro capacity in the area was also utilized in order to obtain the desired frequency change in the minimum amount of time. All other stations were instructed to allow their generation to vary on a basis of governor response.

The first test was made on Friday, December 12, 1947, and the results showed that with a frequency drop of 0.4432 cycles or 0.735 per cent, there was a load drop of 83,500 kw or 1.88 per cent of the average load of 4,437,000 kw for the high-frequency periods. Expanding this frequency drop to a full 1 per cent would indicate a load drop of 2.588 per cent. Unfortunately, there was a misunderstanding regarding the request to take voltage readings on the regulated circuits and at only four of the 106 locations were voltages read on the regulated side of these circuits. While the over-all load drop of 2.588 per cent for a reduction in frequency of 1.0 per cent confirmed prior tests, insufficient data had been taken to determine the load drop resulting from the accompanying voltage reductions.

The second test was conducted on Wednesday, January 14, 1948, when the combined load was 4,500,000 kw or 1.45 per cent higher than at the time of the first test. The period and method of conducting this test was exactly the same. Through better planning, we were able to attain a slightly greater frequency drop of 0.4866 cycles or 0.807 per cent. This resulted in a load drop of 97,000 kw or 2.169 per cent. This figure when expanded to a frequency of 1 per cent, gives a load drop of 2.688 per cent. The calculations of the load drops for both of these tests are of equal accuracy and, therefore, they have been averaged giving a load drop of 2.613 per cent for a 1 per cent drop in frequency.

It is interesting to note that these tests substantiate the results given in a paper prepared by H. Estrada and H. A. Dryar[2] entitled Regulation of System Load and Frequency.

Allocation of the Load Drop

In the second test, voltage readings were taken at 75 unregulated locations and the voltage drop varied from zero to 3.0 per cent. The voltage drops at these various locations have been grouped according to magnitude and plotted on a probability curve, Figure 5. This curve is exceptionally interesting in that it shows that for 10 per cent of the cases the voltage drop was approximately zero. For 50 per cent of the cases the voltage drop was less than 0.92 per cent and for the other 50 per cent of the cases, the voltage drop was greater than 0.92 per cent, thereby indicating that the most probable voltage drop for unregulated locations was 0.92 per cent. This is somewhat less than the average voltage drop which was 1.02 per cent.

The results of the readings taken at 37 locations on the regulated side of regulated circuits showed that the average voltage during the reduced frequency was slightly higher than the average voltage during the high-frequency periods. Seventy-eight per cent of the Public Service Electric and Gas Company's load is regulated. That company reported voltage readings on 15 different regulated circuits and the average voltage on all of

these circuits during the low-frequency period was 0.09 per cent higher than during the average of the two high-frequency periods. Approximately 50 per cent of the Philadelphia Electric Company's load is regulated. That company examined charts from 22 regulated circuits and the average voltage on these circuits during the low-frequency period was 0.03 per cent higher during the low-frequency period.

A special super-sensitive voltmeter was connected to a 4,000-volt regulated feeder in the Baltimore area and no change in voltage was detected as a result of the change in frequency. The only exception regarding voltage change on regulated circuits was in Washington, D.C., where a reduction of 1 per cent in voltage was reported with the frequency drop of 0.4866 cycles. This data was given its proportional weight in the development of the results of the test.

When making the calculations of load drop with frequency variation, it is important that adequate attention be given to the measurement of time. It has been stated previously that the load drop which accompanied the frequency drop in the tests, herein described, was determined from 15-minute integrated readings. The large majority of these readings were taken on electrical time and about 50 per cent of the total load was measured by electric printometers. When the system frequency is running low, printometers will record more than the true load, while when the frequency is high, the opposite will be true. The same condition holds when watthour meter readings are based on time expired as determined from an electric clock. During these tests, 25 per cent of the total load drop did not become evident until the necessary time corrections were made. An analysis of the load reduction by companies for the frequency drop test of January 14 is given in Table I. It illustrates how the average of the two high-frequency periods was compared with the low-frequency period in order to determine the load drop. Furthermore, it indicates that the total load during the second high-frequency period was only 16,000 kw or 0.36 per cent different than that of the first high-frequency period, thereby illustrating the steadiness of the load during the period of the test. Table II illustrates the distribution of load drop due to voltage drop during the period of low frequency.

Conclusion

It is generally conceded that a 1 per cent reduction in voltage will be accompanied by a 1 per cent reduction in load. While a voltage reduction as much as $7^1/_2$ per cent will be generally satisfactory, there are certain locations where it is impractical and the voltage drop must be limited. This establishes a maximum load reduction of about 240,000 kw or a little more than 6 per cent for our co-ordinated operating areas.

A one per cent drop in frequency independent of a planned voltage drop will reduce the load approximately 100,000 kw or approximately 2.6 per cent. Of this 100,000-kw load drop, 70,000 kw or 1.9 per cent is due to the reduction in frequency alone and 30,000 kws or 0.7 per cent is due to the voltage reduction which accompanies the frequency reduction.

Based on the results of these tests, we have been able to establish a definite procedure of both voltage and frequency reduction for the respective operating areas in order that we may carry on under emergency conditions of short duration with a minimum of inconvenience to our customers. The outline of this program for the Pennsylvania–New Jersey Interconnection is as follows:

1. The normal spinning reserve for this area is 236,000 kw.

2. When the spinning reserve drops below 100,000 kw, the interconnection dispatcher issues a "first voltage warning" to all companies, who in turn communicate it to generating stations and attended substations.

3. When the spinning reserve drops below 50,000 kw, the interconnection dispatcher issues a "second voltage warning." This is communicated to all generating stations. Furthermore, regulators in substations in certain areas are blocked, while in other areas, supervisors go to the substations to supervise voltage reduction, should it be required.

4. If and when the spinning reserve drops to zero, and the frequency is dropping, a voltage reduction up to $7^1/_2$ per cent is ordered. In those areas where regulators are blocked and in areas where no regulated circuits are in use, the voltage is dropped at the generating station. In other areas the voltage is reduced manually at the regulator.

5. Should the voltage reduction prove inadequate, the frequency is allowed to drop to 59.4 cycles (1 per cent).

6. Beyond this point, load would be interrupted.

The Baltimore–Washington Interconnection has adopted a load control plan which closely parallels the above plan.

Results of Frequency and Voltage Reduction Tests on an Isolated System*

As in the case of a majority of the electric utility companies in this country, the Kansas City Power and Light Company, serving the metropolitan area of Kansas City, Mo., and surrounding territory, was faced with the problem of a potential shortage in generating capacity. This is due to the inability of utility companies in general to secure added generating capacity during the recent war years and the unprecedented growth in system load following the close of the war. Further, the inability during the war, to remove generating equipment from service for the usual overhauls resulted finally in the need for a program of scheduled outages for maintenance.

Under these conditions, together with the anticipation of still further load increases but before added generating capacity could be installed, it was decided in the early part of 1947 that emergency conditions might require the lowering of system frequency and voltage.

To determine the amount of relief that could be expected from these expedients, tests on the system were conducted on February 20 and March 7, 1947 to actually measure the amount of load decrease that would obtain for a given drop in system frequency and voltage.

The System Tested

The 1946 peak load on the Kansas City Power and Light system was 235 megawatts. All of this load was generated in

* C. B. Kelley and T. W. Schroeder.

Figure 6. One-line diagram of Kansas City Power and Light Company

System as of time tests were made

the two steam plants known as the Grand Avenue Station, with a total generating capability of approximately 106 megawatts, and the Northeast plant with a maximum capability of approximately 166 megawatts. Figure 6 is a simplified 1-line diagram showing these generating plants and the principal connections between them. About 13 megawatts of the system load was 25-cycle traction system requirement of the Public Service Company supplied from Grand Avenue Station. Practically all of the 60-cycle load is fed out of the plants at 13.5 kv to nine large distribution substations, and five synchronous converter stations feeding the downtown d-c area. An idea of the character of the system load may be obtained from the following breakdown:

Type of Load	Per Cent of System Peak
Industrial	44.7
Domestic	14.6
Commercial	27.1
D-C Edison system	7.7
Other utilities	5.9

A stand-by interconnection with the system of the city of Kansas City, Kan., is maintained but there is no normal interchange of power over this tie.

Figure 7. Frequency, load, and voltage charts obtained during tests

Top—March 7, 1947 test
Bottom—February 20, 1947 test

Method of Making Tests

Previous observation indicated the system load was practically constant between 9:30 a.m. and 11:00 a.m. Fortunately this condition prevailed on the days during which tests were made. The tie with the Kansas City, Kan., system was open during the tests.

System load readings were taken from a Leeds and Northrup strip chart totalizing recorder which totalizes the output of each generator on the system. Frequency readings were taken from a Leeds and Northrup frequency recorder. The frequency recorder readings were checked by use of a portable frequency meter and also by measuring the speed of one turbo-generator set by use of a geared tachometer. Prior to the tests the charts of the frequency recorder and the load recorder were adjusted to be in time synchronism.

The system frequency was dropped gradually in approximately uniform steps over the period of the tests. Prior to voltage dropping test men were stationed in those substations having feeder voltage regulators to make the regulators nonautomatic at a given time. Immediately following this the generating plant voltage was dropped in approximately uniform steps by simultaneous changes in setting of the generator voltage regulators. Voltage was held at test values under guidance of a portable indicating voltmeter.

February 20, 1947 Test

The frequency was lowered slowly requiring about 15 minutes time to reach a value of 58.5 cycles.

A brief summary of the load conditions existing prior to and during the test follows:

9:49 a.m.—Frequency normal, 60-cycles
System load, 214 megawatts
Northeast generation, 138 megawatts
Grand Avenue 60-cycle generation, 62 megawatts
Grand Avenue 25-cycle generation, 14 megawatts
Public Service load, 13.7 megawatts

9:49½ a.m.—Operators at each station started lowering frequency

10:05 a.m.—Frequency, 58.5 cycles
System load, 204 megawatts
Northeast generation, 132 megawatts
Grand Avenue 60-cycle generation, 59.5 megawatts
Grand Avenue 25-cycle generation, 12.5 megawatts
Public Service load 12.5 megawatts

10:10 a.m.—Operators at each station started increasing frequency

10:14 a.m.—Frequency normal, 60 cycles
System load, 214 megawatts
Northeast generation, 135 megawatts
Grand Avenue 60-cycle generation, 62.5 megawatts
Grand Avenue 25-cycle generation, 16.5 megawatts
Public Service load, 13 megawatts

Total load dropped as result of decreasing frequency 10 megawatts
Drop in frequency was 2½ per cent
Drop in load was 4.68 per cent

Figure 8. Curves prepared from test data

Top — Variation of load with frequency

Bottom—Variation of load with voltage

During the tests, additional readings and observations were made of boiler and turbine auxiliaries. No instability in operation of this equipment was observed at either station. The reduction in frequency was not noticed by the customers as not a single complaint was received.

March 7, 1947 Test

As in the previous test the condition of very nearly constant system load prevailed prior to the time selected for the test.

The test was conducted in two steps. The first consisted of lowering the 60-cycle bus voltage at Northeast Station, and the 60-cycle and 25-cycle bus voltages at Grand Avenue Station, approximately 3 per cent. The second step consisted of lowering the system frequency one cycle, while maintaining the bus voltage at 3 per cent below normal.

A few minutes prior to the start of this test, the voltage regulators on all 4,000-volt feeders out of substations having feeder regulators were set on "nonautomatic," in the position in which they were found.

As a safety measure neither Northeast Station or Grand Avenue Station were fully loaded during this test. The Kansas City, Kan., tie was opened a few minutes prior to the test, and remained open during the entire test period.

The lowering of voltage and frequency resulted in no complaints from the customers, and mechanical department reported that conditions in the boiler rooms were stable.

Following are shown the system conditions relative to frequency, voltage, and load in each of the generating stations prior to and during this test:

9:51 a.m.—Frequency normal, 60-cycles		
Bus voltage Northeast number 1 section	13,830	volts
Bus voltage Grand Avenue number 1 section	13,600	volts
System load	209,900	kilowatts
Northeast generation	134,000	kilowatts
Grand Avenue 60-cycle generation	60,000	kilowatts
Grand Avenue 25-cycle generation	15,900	kilowatts
Public Service load	14,500	kilowatts
10:00 a.m.—Frequency normal, 60-cycles		
Bus voltage Northeast number 1 section	13,390	volts
Bus voltage Grand Avenue number 1 section	13,200	volts
System load	204,000	kilowatts
Northeast generation	130,000	kilowatts
Grand Avenue 60-cycle generation	60,000	kilowatts
Grand Avenue 25-cycle generation	14,000	kilowatts
Public Service load	13,300	kilowatts
10:16 a.m.—Frequency 59.0 cycles		
Bus voltage Northeast number 1 section	13,415	volts
Bus voltage Grand Avenue number 1 section	13,200	volts
System load	198,000	kilowatts
Northeast generation	126,500	kilowatts
Grand Avenue 60-cycle generation	58,000	kilowatts
Grand Avenue 25-cycle generation	13,500	kilowatts
Public Service load	12,600	kilowatts
10:32 a.m.—Frequency normal, 60 cycles		
Bus voltage Northeast number 1 section, normal	13,800	volts
Bus voltage Grand Avenue number 1 section	13,600	volts
System load	210,000	kilowatts
Northeast generation	135,000	kilowatts
Grand Avenue 60-cycle generation	60,500	kilowatts
Grand Avenue 25-cycle generation	14,500	kilowatts
Public Service load	12,500	kilowatts

Test Data

Figure 7 (bottom) shows the portion of the frequency, load, and voltage charts obtained during the period from 9:49 a.m. to 10:14 a. m. during the February 20, 1947 test. Figure 7 (top) shows the same charts for the March 7, 1947 test from 9:51 to 10:32 a.m.

From these charts the data of Figure 8 was prepared. Figure 8 shows the variation of load with frequency for the February 20 test and with voltage during the March 7 test and also the variation of load with frequency at reduced voltage as obtained from the March 7 test.

Summary of Results

During the February 20 test, with system load fairly steady at 214 megawatts and normal frequency of 60 cycles, the frequency was gradually dropped over a 15-minute period to 58.5 cycles and the load dropped to 204 megawatts. This represents a frequency drop of 2.5 per cent and corresponding load drop of 4.68 per cent, or about 1.87 per cent load reduction per cent frequency reduction, or approximately 0.31 per cent per 0.1 cycle frequency reduction.

On March 7, the same system was tested to determine the effect of dropping voltage and also the effect of dropping frequency with lower than normal voltage obtaining. With a load of 225 megawatts and normal voltage the voltage was dropped 3 per cent below normal and the load decreased to 218 megawatts, 1 per cent load decrease for 1 per cent voltage decrease. With the voltage 3 per cent

below normal and the load at 218 megawatts the frequency was dropped 1 cycle and a further load decrease of 6.5 megawatts resulted, or about 1.78 per cent load drop per cent frequency drop under the reduced voltage condition.

Conclusions

The results of the tests of February 20 and March 7 indicate that system load reductions in appreciable amounts can be safely effected by lowering system generated voltage and frequency.

Based upon a system load of 225 megawatts, the following results can be expected with certain changes in voltage and frequency as shown below:

1.
Assuming a system load of 225 megawatts.
Lower system primary voltage 3 per cent with 4.0 kv automatic station regulators on nonautomatic.
Result—load decrease of 7 megawatts.

2.
Assuming a system load of 218 megawatts and voltage 3 per cent below normal.
Lower system frequency one cycle.
Result—load decrease of 6.5 megawatts.

This is a total drop in load of 13.5 megawatts, or approximately 6 per cent.

It should be possible to lower the system primary voltage as much as 5 per cent, and at the same time decrease the system frequency $1^1/_2$ cycles. Using the same base value of 225 megawatts and assuming the same conditions as stated before, a reduction of approximately 21 megawatts, or 9 per cent, could be expected, provided the regulators in the substations are set on nonautomatic. If sufficient time is available to do so, the regulators in the automatic stations can always be set on the nonautomatic position. However, an emergency might arise where this could not be done, in which case the per cent drop in load due to decrease in the voltage would not equal 1 per cent, but would possibly be in the order of 0.3 to 0.6 per cent drop in load for each 1 per cent drop in voltage. Even under this condition, the lowering of the voltage and frequency is a practical and effective method of relieving the system under emergency conditions.

Discussion

E. E. George (Ebasco Services Incorporated, New York, N. Y.): In the tests reported in the paper under discussion, it does not appear that use has been made of a method developed by the Northwest Power Pool for the elimination of major errors due to gradual changes in the total of customer's loads during the test. This method consists in varying frequency and voltage back and forth repeatedly so that a plot of the results would give a sawtooth or zigzag effect. By drawing curves through the upper and lower series of points, there is established a band whose average width is a good measure of the true effect of voltage or frequency reduction on generating requirements.

There now seems to be general agreement on the effect of voltage reduction. Perhaps the system engineering committee may now consider this project finished with satisfactory results. There is no general agreement on the effect of frequency reduction and there likely can be none except in cases where the percentage and type of power load is very similar. It would be interesting to secure reports of tests from some of the companies in the southwest, where power load is predominant.

One reason some systems give for lack of interest in frequency reduction is that in most cases frequency reduction is either difficult or impractical. However, frequency reduction is going to occur even when not intended and engineers should know what is going to happen. Unfortunately, they have made most of their tests to find out what would happen on customer's premises and the resultant effect on generating requirements. Sufficient information has not been obtained on the effect of low frequency on generating plant auxiliaries. The loss of auxiliaries generally means a heavy interruption of service to customers. In some cases, this is far more important than what low frequency does to customer's equipment. It is suggested that the committee promote tests on power plant auxiliaries. It is desirable to known how present designs of plants perform, what minor changes can be made at slight expense, and what major changes in design would be required to take care of emergency frequency conditions as low as 57 cycles.

Eric T. B. Gross (Illinois Institute of Technology, Chicago, Ill.): It is very interesting that these valuable papers are in fairly good agreement with each other. It is difficult to predict the changes of composite loads without tests, since the change of the motor input depends largely on the motor type and on the torque-speed characteristics of the load. We know how each type of load reacts under voltage—and/or frequency drops, but the behavior of mixed loads of unknown composition can be found only by tests.

It seems to me that voltage reduction is somewhat simpler than frequency reduction. It is realized that the problem of today's emergencies is more of a megawatt problem than a megavolt-ampere problem. In other words, we lack boiler capacity in steam plant and water supply in some hydro-systems. However, it should be kept in mind that frequency reduction without equal per unit voltage reduction leads to increased reactive megavolt-ampere, and a word of caution seems appropriate with regard to the rating of the equipment in megavolt-ampere. Certainly, the measures discussed here will lead to a decrease in megawatt, but we may not always be able to permit an increase of current or megavolt-ampere that could be brought about by frequency drops.

James M. Comly and H. W. Phillips: It is most gratifying to the authors that their paper has aroused the general interest indicated by the excellent discussions which have been presented. We are particularly happy to receive the information from T. E. Curtis of the Pacific Gas and Electric Company concerning that company's experience with extended periods of reduced frequency operation.

In response to the first comment by E. E. George of Ebasco Services, it should be pointed out that a paper by Estrada and Dryar[1] described the method which he mentions for eliminating major errors due to gradual change in the total of customers loads during tests. Phillips, in our paper, notes that the results of the tests made by the Pennsylvania–New Jersey and Baltimore–Washington Interconnection substantiate the results given in the earlier paper by Estrada and Dryar. We agree with George that further test and design data are necessary to get reliable data on the effect of reduced frequency on station auxiliaries and through them on station capacity. The experience of Commonwealth Edison mentioned by T. E. Gault adds to the available data.

The question raised by Professor J. R. Hafstrom of the University of Wisconsin concerning equipment dependent on instantaneous frequency for their operation is very disturbing since it indicates a tendency on the part of designers of specialized equipment which may lead to disastrous results. We want to make it very clear that an electric power utility is designed to produce and to sell kilowatts and kilowatt-hours for light and power, and is not designed to supply or sell precision frequency or time. Large additional investment and considerable redesign would be required to make our present systems suitable for supplying precision frequency and time in addition to power and light.

It is true that in their normal operation the power utilities usually hold frequency so closely to its nominal value that timing devices which depend upon system frequency for their accuracy may be used satisfactorily. It is also true that under normal conditions electric systems operate in synchronism over wide areas. However, both of these conditions exist because they aid the utilities normally in the safe and economic operation of the systems to supply power and light. In an emergency, any part of an interconnected system may be separated from the rest of the system electrically without warning to the customers and may be operated as an isolated system for an indefinite period. Similarly, changes in frequency several times greater than normal may occur at any time without warning to individual customers. The designers of radar flight control devices or any other devices which must operate continuously to protect life or property should know that there can be no guarantee that utility system frequency will remain constant. If it does remain constant it is for the benefit of the operators of the system and not as a part of the service the utility undertakes to supply its customers.

Eric T. B. Gross of the Illinois Institute of Technology in his discussion emphasizes the fact, mentioned in the introduction to our paper, that reduction in frequency without corresponding reduction in voltage will cause an increase in reactive load. Because of this fact the megavolt-ampere rating of the generators must be considered as well as the megawatt rating.

The discussions as well as the data presented in the paper confirm the belief that voltage reduction is usually a safer and more convenient method than frequency reduction for shedding load in an emergency brought on by the loss of reserve generating capacity. In special cases, a combination of voltage and frequency reduction may be desirable. Such a special case might be a system of such extent and design that it does not require automatic frequency with tie line load bias control. Another example might be a system having a load of such composition that the load is unusually sensitive to changes in frequency. In most cases, however, frequency reduction may lead to reduction in capacity, unnecessary loss of revenue, and undesirable complications in the operation of system ties.

T. W. Schroeder and C. B. Kelley: The discussions seem to conclude that while voltage reduction is a satisfactory means of load reduction, frequency reduction is not similarly so. It is evident that the effectiveness of frequency reduction is quite variable and dependent upon the make-up of the composite system loads. It would appear that the load decrease with frequency increase, result of the tests reported by Comly, is due to a predominance of refrigeration load on the portion of the Consolidated Edison system tested. On the other hand our tests, though of short duration, and Phillips' results indicate load reduction with frequency reduction. The results reported by T. E. Curtis of Pacific Gas and Electric Company indicate load reduction with frequency reduction during the critical drought period affecting his company's system last spring. This, in spite of a considerable portion of pumping load, regarding which it is reasoned that if frequency is reduced, the pumps run slower, but run longer until the right amount of water is obtained.

Contrary to the feeling that voltage reduction is preferable because it would affect fewer customers, it is our belief that if practicable, frequency reduction would be best from the customers' standpoint because it would affect all customers only slightly. Further, if frequency reduction on an interconnected system is possible, a comparatively small frequency reduction might result in a reduction of load of a large number of kilowatts, although of only a small percentage of a large load.

E. E. George's comments regarding the desirability of determining the effect of fre-

quency reduction on power plant auxiliaries, particularly at times when the plants are running near absolute maximum capability, is worth-while. At present we consider the possibility of a reduction in plant output to be the chief reason for dropping frequency no lower than to about 58.5 cycles during emergencies.

Further knowledge regarding performance of auxiliaries would point the limiting equipment and the actual lower limit of frequency reduction.

Continuous Load-Frequency Control for Interconnected Power Systems

H. M. DIMOND

G. S. LUNGE
ASSOCIATE AIEE

Synopsis: Functioning in response to integrated deviation from a tuning fork-controlled standard frequency, and biased by deviation from scheduled tie-line load as telemetered to this location, this improved load-frequency control equipment provides continuous comparison of system frequency and tie-line load with their respective scheduled values. This continuous comparison, in conjunction with strict proportionality between deviation and correcting effect on the prime mover governor speed level adjustment, has proved in several years of service to be beneficial in minimizing governor and inlet valve movement and hence wear, as compared with the periodic intermittent correcting impulses used in earlier types of frequency controllers, even of the integrated-deviation type. The use of integrated frequency deviation as the quantity to which the controller responds inherently eliminates frequency deadband, but the tie-line load controller retains an adjustable deadband to render it oblivous of inevitable minor oscillations in tie line loading.

LOAD-FREQUENCY control is the automatic regulation of the frequency of a power system, or portion thereof, to keep the frequency within a narrow range and at the same time maintain approximately constant the kilowatt loading of one or more tie lines leaving the system, or portion thereof.[5,8] Where no such tie lines exist or their loading need not conform to a definite schedule frequency control only is applicable.[1,2] Where no attempt is made to have the generating station or stations concerned share automatically in the task of maintaining the system frequency approximately constant but maintenance of tie-line loading is considered important, tie-line load control only may be used,[2,4,6,10] either in response to the voltage vector phase angle existing between corresponding voltages at opposite ends of the interconnection[4] or, more commonly, to the totalized kilowatt loading of all tie lines between the two systems or portions thereof.

Today in extensive system interconnections, instead of assigning the task of frequency control exclusively to one station, it is the usual practice[11,12,14] to provide automatic load-frequency control equipment for all stations that are to have automatic regulation of output, in order that all stations controlled may participate to some extent in the task of maintaining system frequency constant. This procedure usually takes the form of tie-line bias control,[8,13] in which the automatic controller responds neither to frequency only nor to tie line load deviation from schedule only, but to a combination of the two, in adjustable proportion. With this type of control, all of the controllers on the system will not be satisfied until the frequency is correct and all tie-line load schedules are being fully maintained. However, if both the frequency and tie-line loading depart from scheduled values, the controller will not initiate correction of frequency at the expense of causing further deviation from scheduled tie-line loading, or vice versa. Instead, if the deviation from tie-line load scheduled value is in such direction and amount as to be certain to disappear automatically if and when the frequency returns to normal, the controller will not initiate any correction but will let nature take its course, with consequent substantial reduction in wear and tear of prime mover governor and valve mechanisms as compared with endless conflicting action of tie-line load controllers and frequency controllers. The former device cannot perceive whether the tie-line load change from schedule is such as to disappear automatically later without controller action, and the latter device tends to make the same correction for a given load change on the system, regardless of whether the load change occurred on the system regulated or on the neighboring system at the other end of the tie lines, two situations requiring entirely different treatment if tie-line load schedules are to be maintained as closely as possible.

Purpose of Load-Frequency Control

Close maintenance of 60-cycle frequency by power systems has been found to be of major assistance in many phases of system operation, particularly in maintaining scheduled power interchange required by contractual relationship with sources of purchased power or with customers having some generating capacity of their own. The operation of electric clocks, time switches, and other synchronous motor driven devices is obviously facilitated by closely regulated frequency being maintained, though this is usually a minor aspect of the application of such equipment.

If automatic frequency control equipment were applied to a large enough proportion of the generating capacity connected to the system, occasional manually-performed changes in prime mover output would become unnecessary. However, so far, most power systems using automatic load-frequency control equipment depend on it only to take care of minor variations in system load that would have an adverse effect on the frequency and would be extremely exacting in their demands on any human operator who might attempt to correct for such changes. Accordingly, the usual present practice is to make the load-frequency control equipment relatively slow in response so that

Paper 48-268, recommended by the AIEE system engineering committee and approved by the AIEE technical program committee for presentation at the AIEE Mid-west general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted August 4, 1948; made available for printing September 7, 1948.

H. M. Dimond is development engineer and G. S. Lunge is with the central station engineering division, both with the General Electric Company, Schenectady, N. Y.

the controller will only intervene in the so-called fourth stage of system load division upon the occurrence of a load change. The first stage of load division takes place in a manner determined by the electrical impedances from the generators to the load that has changed, the second stage in a manner determined by the amount and geographical distribution of stored energy in the generator units with their associated prime movers, and in the third stage the action of the speed governors modifies the load division in accordance with the governor characteristic slopes. In the fourth stage of load division, the governor characteristics are modified by their synchronizing motors under control of the load-frequency controllers.

If all tie lines were of ample carrying capacity and stations under automatic frequency control well distributed geographically throughout the area, aside from exceptional situations where contractual relationships fix tie-line interchange power schedules, there would be no need for tie-line load control. With the advent of system interconnection on a larger scale, and the insistence on more efficient operation of tie lines, the tendency in recent years has been to insist on load-frequency control rather than frequency control, sometimes called flat frequency control.

Figure 2. Block diagram of frequency and tie-line load control system

Basic Types of Frequency Control Equipment

In this country, frequency control equipment has been usually of one of two types. The most generally used type responds to deviations from instantaneous frequency and automatically corrects the prime mover speed level settings at a rate at least approximately proportional to the deviation from normal frequency (60 cycles). The standard reference frequency usually takes the form of an a-c frequency measuring bridge as used in conventional frequency recorders. When, for more accurate clock operation, automatic time error correction is required, this is accomplished by automatically recalibrating the frequency bridge in the frequency controller, with the aid of a time error indicator operated from a tuning fork controlled source of standard frequency.

In another type of automatic frequency control equipment, the prime mover governors are automatically readjusted in proportion to the integrated deviation from the standard reference frequency. In the usual construction of this type of frequency control equipment, the load on each unit controlled is made directly proportional to a few seconds time error that is intentionally permitted to accumulate between the condition of daily minimum load and daily peak load, this time error disappearing automatically as the system load decreases. This makes it unnecessary to measure the output of each controlled unit and convey this information back to the frequency controller.

Intermittent versus Continuous Frequency Control

From the nature of its operating principle, that is, frequent periodic comparison of system frequency with the standard value, frequency control systems func-

tioning in response to deviation from instantaneous frequency send correcting signals in the form of impulses to correct the governor settings as required.

In frequency controllers responding to integrated deviation from standard frequency, in which the standard frequency was established by a pendulum, corrections were likewise made in the form of impulses originated, when necessary, on each swing of the pendulum in a given direction.

In more recent years, in order to obtain the advantage of smoother and less rapid prime mover governor and gate operation under automatic frequency control, the integrated-deviation type of frequency controller was redesigned so as to use a tuning fork controlled source of standard reference frequency, instead of a pendulum. This change is analogous to the modern trend toward continuous action generator voltage regulators instead of the intermittent-action type. By means of a differential Selsyn having a 3-phase winding on both stator and rotor, the standard reference frequency and a system frequency are continuously compared, any difference in frequency resulting in rotation of the shaft of this Selsyn. Such rotation of the shaft is communicated by other Selsyns of conventional type to the prime mover governors, ordinarily by means of a governor Selsyn unit that utilizes the normal synchronizing motor as the source of torque for such readjustment but establishes a fixed relationship between the number of revolutions of the shaft of the comparing Selsyn and the number of revolutions of the synchronizing motor resulting therefrom, 60 revolutions of the differential Selsyn (comparator) usually corresponding to a change in governor adjustment from no load to full load at rated frequency (60 cycles).

Such continuous comparison eliminates any deadband in the controller, as even a very minute drift in frequency will be perceived by the differential Selsyn. As in the case of the earlier intermittent type of integrated deviation frequency controller, time error correction is inherent and automatic, so that the only manual time error correction necessary is that occasioned by errors in the standard frequency as compared with correct astronomic time, or corrections necessary as the result of the automatic frequency control equipment getting out of range, that is, having insufficient generating capacity under its control to make the required correction in machine output.

Load-Frequency Control

In its original form, even the continuous type of integrated deviation frequency controller did not take into consideration the tie line loading, that is, was only suited to flat frequency control. The remainder of this paper is devoted to a description of the requirements for which a load-frequency controller of this type was designed to incorporate tie line load bias, and how these requirements were met.

The following general requirements were selected as offering those features most desirable in an automatic frequency and tie-line load system.

Frequency Control

1. Frequency control must be accomplished smoothly with no sudden changes in the governor setting. This feature is very desirable to minimize wear and maintenance on governor and control parts.

2. The frequency sensing device must be sensitive to any frequency deviations no matter how small because a small frequency error maintained for a time can accumulate into a considerable time error.

3. The rate of frequency correction must be proportional to amount of deviation of system frequencies from standard time base.

The Line Load Control

1. Control must operate from telemetered signals.

2. Control must be adjustable for a wide range of operating conditions. It must have adjustments to allow for a range of control of proportional bias rate, maximum bias rate setting, deadband, and base load. The limits, slopes, and so forth for the "raise" side of the dead band and those for the "lower" side must be able to be set independently and any single adjustment must not affect other adjustments by an appreciable amount. The frequency and tie-line load control must be able to operate either as flat frequency or flat tie-line load controls or as frequency control biased by tie-line load. The amount of bias should be adjustable over wide ranges to accommodate a wide variety of operating conditions.

In setting up these specifications the latest concepts of efficient power interchange methods were carefully considered. Another consideration was the important objective of designing a control system which would do the right thing at the right time without the necessity for the system to frequently readjust itself. Figure 2 shows a block diagram for the frequency and tie-line load control system developed to meet the foregoing specifications. The system consists of a standard frequency source, a frequency comparator, a means for transmitting the signal from the frequency comparator to the governor control, a tie-line controller, and a means for converting this tie-line load controller signal to a form which can be used to bias the frequency control signal.

The standard frequency supply consists of a tuning fork oscillator and its associated electronic circuits which control the speed of a motor generator set. In the frequency comparator a 3-phase differential Selsyn provides a frequency sensing device with no deadband. It also provides an output signal

Figure 6. Partial simplified circuit diagram of tie-line load control and bias motor control circuits

Figure 7. Tie-line load controller performance curves showing range of dead band adjustment obtained by spacing of center contacts

that is proportional to the frequency error signal integrated with respect to time. The 3-phase output of the motor generator set is applied to the stator winding of the Selsyn and the rotor windings are connected to the system to be controlled. As long as the frequency of the two systems is exactly the same, the shaft of the differential Selsyn will remain stationary. Any difference in frequency between the system and the standard will cause the shaft to turn at a speed and in a direction proportional to the amount and direction of the frequency difference. A frequency difference of one cycle per second will cause the rotor to turn at a speed of one revolution per second. The rotation of the Selsyn shaft is transmitted through the differential gear box to the master Selsyn. The signal from the master Selsyn is communicated electrically to the governor Selsyn unit. As the governor Selsyn rotates in response to the signal received from the master Selsyn it turns a threaded shaft. A follower on this shaft is carried along the axis of the threaded shaft, (Figure 3). A single-pole double-throw vacuum switch is operated by the linear motion of the follower and energizes the governor synchronizing motor to adjust the governor in the proper direction to correct for the frequency condition then in existence. As the governor synchronizing motor runs, its action is fed back through a gear reduction to the previously mentioned follower on the threaded shaft of the governor Selsyn unit. The follower is rotated in a direction to return it to its original position, thus opening the vacuum switch and stopping the synchronizing motor. The above arrangement will "remember" the number of revolutions made by the governor Selsyn and cause the governor synchronizing motor to make exactly the corresponding number of revolutions. The "memory" feature nicely eliminates any necessity for correction to allow for the time lag in starting and stopping the synchronizing motor. The governor Selsyn unit is equipped with a magnetic clutch so that under extreme conditions when the governor synchronizing motor has reached the limit of its control range, and the automatic control is still calling for governor adjustment, the magnetic clutch will slip and no damage to the control parts will result. The clutch is also used for disconnecting the control when manual changes of governor setting are made.

During a condition where a machine has reached one of its load limits, time will be lost or gained and a resulting time error will accumulate. In order to conveniently correct this accumulated time error the time bias motor is provided on the frequency comparator unit, Figure 4. The time bias motor operates through the differential gear in the frequency comparator unit and its function is to introduce a small bias so that even though the system frequency is exactly the same as the standard frequency and the differential Selsyn shaft is stationary, the master Selsyn will be rotated very slowly in a direction to steadily but slowly urge the system to correct for the accumulated time error. The motor used for the time bias correction is also used for tie-line load bias and in the latter function the bias motor speed is controlled by the tie line load controller.

The signal to the tie-line load controller is obtained from the new frequency-type telemeter recently announced by the General Electric Company,[17] and the input to the photoelectric load controller is d-c milliamps. The photoelectric load

Figure 8. Tie-line load controller performance curves showing range of adjustment of point of maximum correction rate obtained by changing potential across potentiometer

controller is similar in operation to the standard General Electric photoelectric recorder.[14] The recording pen for the photoelectric recorder has been replaced by a contact arm riding on the wire winding of the potentiometer, Figure 5. The mechanical zero set of the basic instrument has been made readily adjustable and is geared to the dial pointer to indicate and set scheduled load on the tie line. In operation the basic instrument zero setting is biased by this adjustment by an amount which will require a telemeter signal corresponding to the scheduled tie-line load to hold the pickup arm at the center of the potentiometer. A deviation from schedule will cause a deflection of the arm proportional to the deviation. The photoelectric recorder system is used merely as a torque amplifier to enable the movement of a low-torque type instrument to be transferred with enough power to move a contact across the potentiometer. The photoelectric-recorder type torque amplifier system provides a very dependable and time-proved method for accomplishing this.

Figure 9. Tie-line load controller performance curves showing range of correction rate slope by adjusting position of outside contacts on potentiometer

Figure 1 shows a view of the rear of the control cabinet and the location of the various components. It should be noted that this particular installation provided two separate frequency controls and one tie-line load control unit. The two frequency control units are duplicates; the tie-line load control is used with either.

Only a partial circuit diagram is shown in Figure 6. The complete circuit diagram is complicated by switching circuits, and so forth, and is not needed for an understanding of the operation of this system. D-c potential is applied to a linear wound potentiometer as shown, so that the exact center of the winding is at zero potential with respect to the circuit and a deflection of the pickup arm to the left would produce a negative potential on the arm and to the right a positive potential. When scheduled tie-line load is being held, the pickup arm will be in the center of the potentiometer and the potential of the arm will be at zero. When the pickup arm is at zero the bias motor is stationary. The potential of the pickup arm for any given deflection is determined by the relative position of the center and outside contact points and the voltages across these two points. Contacts are shown in Figure 5, with the adjusting screws for positioning the contacts. Since the two center contacts are connected together, any distance spanned by them on the potentiometer will be at zero potential and determines the deadband region. For any fixed voltage applied between the center contacts and one of the outside contacts of the potentiometer, the output signal voltage of the pickup arm for any definite deflection will be proportional to the distance between the center contact and the outside contact, thus a wider separation between these two contacts results in a smaller signal increase for any definite increment of tie line load signal.

The position of the outside contact will also determine the deflection point at which the maximum potential will be reached. Thus, from the tie-line load control a signal is obtained which varies in voltage magnitude and polarity as the tie-line load varies and the proportionate amount of this variation is adjustable over a wide range. This signal is used to operate thyratron circuits which control the speed and direction of the load bias motor rotation. The direction of rotation depends upon which of the two thyratrons is operating and the speed will be dependent upon the amount of current passed by the thyratron. Refer again to the circuit diagram, Figure 6. The plate current of these thyratron tubes depends upon the phase relationship between the grid and plate a-c voltages. If the two are in phase a large current will pass and if out of phase no current will pass. The phase relationship between the grid and plate of these tubes is varied by phase shift in the bridge circuit feeding the tube grids. Each phase shift circuit consists of several resistors and a saturable reactor. A small change in the direct current of the saturable reactor control winding will cause a considerable change in the phase of the voltage applied to the thyratron tube grid. Rectifiers in the output of the controller are arranged so that a positive signal from the control actuates one saturable reactor and a negative signal actuates the other. The amount of signal determines the resulting phase shift which in turn controls the output current of the thyratron tube. In order that the speed of the bias motor will be proportional to the signal obtained from the photoelectric control, and will not vary appreciably with motor load, a small feed-back generator is connected to the bias motor. A portion of this generator output is connected to oppose the signal applied to the saturable reactor control winding. This provides, in addition to a speed proportional to the potential impressed on the control circuit, a positive antihunt circuit which operates very effectively. In Figures 7, 8, and 9 are shown the characteristics of the tie-line load control. In these figures full speed of the bias motor corresponds to a correction rate of "no load" to "full load" governor setting in five minutes. These three figures show the range of correction rate settings available and the many adjustments that can be made in this control equipment. They show that the deadband can be adjusted from zero to approximately 20 per cent of full load range, that the correction rate slope can be set for a wide range and the maximum correction rates are adjustable from 100 per cent speed to 0 per cent speed for the

bias motor. With these adjustments, it is possible to meet nearly any operating condition requirement and provide a smooth control of a type which allows a maximum efficiency of operation with minimum requirements for maintenance.

The signal from the differential Selsyn and the signal from the bias motor are combined in the differential gear before going to the master Selsyn so that signal to the governor Selsyn is the sum of the two. The systems may be operated "flat frequency" or "flat tie line load" by switching off one or the other system.

The signal from the master Selsyn can be used to control any number of governor Selsyn units, so the addition of more generators under control requires only the addition of a governor Selsyn unit for each generator.

Conclusions

The continuous-comparison load-frequency control equipment has the following novel features compared with earlier equipment operating on the same integrated frequency-deviation principle:

1. Standard reference frequency is a tuning fork controlled source, instead of being established by a pendulum.

2. Comparison between system and standard frequencies is continuous and results in a proportionate correction in prime mover governor adjustment, instead of taking place only during a brief part of each forward swing of a pendulum.

3. Tie-line bias, in adjustable amount, now is included.

4. The tie-line load controller can operate either on flat tie-line control or tie-line bias control, by throwing a switch.

5. The tie-line load controller, of photoelectric construction, continuously compares the tie-line loading, measured locally or telemetered, with its scheduled value, but only initiates proportional correcting action in case of deviations outside the adjustable deadband.

6. Instead of raise or lower impulses, the load-frequency control equipment originates a continuous proportional correction for the governor Selsyn units, thus making less rapid changes in governor adjustment necessary to accomplish the same resultant change in speed level setting.

7. By telemetering the tie-line load deviation from schedule to several generating stations each containing load-frequency control equipment, several stations can be regulated simultaneously. Due to the good agreement of tuning forks, discrepancies between stations for this reason will cause load changes of much smaller order than inevitable changes due to other causes.

Like earlier equipment operating on the same integrated frequency-deviation principle, the described load-frequency control equipment is characterized by:

8. No deadband for frequency deviations from schedule, even slow drifts in frequency being detected and eventually corrected.

9. No need for bringing a measurement of each controlled generating unit output to the load-frequency control equipment for verifying load division.

10. Time error is corrected automatically daily as long as the controlled generating units remain within their regulating range. Slight differences between astronomically correct time and tuning fork standard time must be corrected manually.

11. Load division between simultaneously controlled units is automatic, requiring no supplementary equipment, as all load increments are divided between machines in strict proportion to their ratings, regardless of any initial intentionally unequal base loads on them, as long as the permissible regulating range of each unit is not exceeded.

Discussion

O. R. Bulkley (Southern California Edison Company, Los Angeles, Cal.): The paper by Dimond and Lunge presents an interesting description of new tie-line load control equipment which would operate on a somewhat different principle than the control which is in quite general use today.

That part of the control for the regulation of flat frequency as described in the paper is essentially the same as the General Electric frequency control presently in use by the Southern California Edison Company for its three 82,500-kw units at Hoover Power Plant. This equipment has been in service since 1939 and its operation has been very satisfactory. Of particular note is the small amount of service and maintenance that has been necessary on the control equipment itself.

It is not felt that there has been any appreciable maintenance required on governors or their servo motors as a result of frequency controller operation, either with the above control equipment at Hoover or with the conventional control in other generating plants on the company's system.

Henry E. Warren (Lombard Governor Corporation, Ashland, Mass.): The paper by the authors describes a device very similar in certain respects to the Precise Turbine Governor recently published.[1]

A hydraulic governor controlling a small turbine with convenient arrangement for load variations and interconnections with the New England Power System through the Boston Edison Company has demonstrated conclusively many of the arguments in both papers.

In the Dimond-Lunge basic controller for flat frequency alone as in the precise governor, continuous comparison is made between system frequency and frequency derived from a standard. In the former case the standard is a tuning fork and in the latter a vibrating wire similar to that used for the control of the Mount Palomar telescope. Both of these frequency standards are capable of very high precision but the tuning fork frequency has a practically fixed value while the vibrating wire is intentionally arranged so that its frequency value can be altered instantaneously over a range of several percent.

The tie between the vibrating tuning fork and the servo-motor of the hydraulic governor in the Dimond-Lunge arrangement is through a motor generator set serving as a power amplifier of the tuning fork frequency and then through a differential Selsyn unit which compares the standard frequency with the generator frequency and through a

transmitting Selsyn to the regular speed controller of the governor which is arranged as a follow-up of the latter Selsyn. In the precise governor the frequency of the vibrating wire is electrically amplified and comparison is then made by a differential Selsyn or an equivalent. The result is transmitted through a pair of Selsyns directly to the governor system without the interposition of a speed control motor follow-up.

The Dimond-Lunge controller introduces load control as a factor to modify speed control only by introducing it in their tie-line control auxiliary. In the precise turbine governor an element of load control is introduced directly with the minimum amount of complication and without requiring any tie-line controller by automatically biasing the vibrating wire. In this way the precise governor will operate with the same general characteristics as existing governors because it develops a speed droop characteristic of the same nature.

It is well to bear in mind that a very large proportion of all governors at present are of the so-called speed droop type operating without tie-line controllers and for the time being new apparatus must live comfortably with this situation.

Tie-line control is desirable without a doubt in a certain proportion of power plants and where such tie-line control is installed either the Dimond-Lunge controller or the precise governor can function satisfactorily. In power stations where automatic tie-line control is a factor the general characteristics of both governors would be about the same although the Dimond-Lunge arrangement seems to be somewhat more complicated.

C. K. Duff (Hydro-Electric Power Commission of Ontario, Toronto, Ont., Canada): The development described in this paper creates a new system of load-frequency control generally applicable to power systems and interconnected networks. The new system based on integrated deviation from a standard reference frequency differs from the system now generally used which responds to deviations from instantaneous frequency. A third system proposed by T. E. Curtis and W. M. Pickslay[1] tolerates a much narrower band of deviation and demands much higher speed of control than either of the others. Three such basically different systems of control are mutually incompatible in any interconnection of power systems, so that any system of control which is to replace one which is already established on extensive power networks must exhibit marked superiority not only in theory but also in ability to meet practical operating conditions. If the new system has been tried in continuous commercial service the results of such tests would be a valuable aid in assessing its merits.

Frequency control based on integrated deviation from a standard pendulum clock, and loading of regulating generators in proportion to such deviation has been tried, formerly on a basis of approximately one second deviation for full load change on the generators. The present paper speaks of "a few seconds" time deviation between maximum and minimum loading. It would be interesting to know if the larger time droop has been found preferable in actual operation or whether the variations of independent time standards dictate a greater time droop in order to avoid unintended load shifting between generators. Time-keeping ability inherent in the integrating principle, with zero dead band, and minimum corrective action to reduce wear of control equipment are advantages experienced by the Hydro-Electric Power Commission of Ontario as described elsewhere by this discusser.[2]

It might have been possible to apply the integrating principle to tie-line load control as well as to the frequency element instead of introducing dead band to minimize control activity. Integration would tend to ensure scheduled energy transfer over ties. However, if dead band is used, its ready adjustability is a decided advantage.

Provision has been made for the inevitable condition of generators reaching their control limits and allowing time to drift beyond the normal band. The biasing motor used for time correction is also used for tie-line control, but the two controls presumably cannot act concurrently, and tie-line load would be left to drift while time bias is in operation. Further, unless the transfer to time bias were made simultaneously at all control stations the effect on tie-line loads might be appreciable. Automatic simultaneous transfer at a predetermined time deviation would seem impractical on account of differences in the reference standards. Concerted manual transfer would be the alternative, not easy on a large interconnection.

It may be noted that the control equipment as described would need to be installed in or near each and every generating station to be controlled, with tie-line telemetering to each of such stations, and the settings and adjustments would need to be made by the operators at such stations. While the instantaneous type of control now widely used may be similarly installed in each generating station, it may be and frequently is installed at a central supervisor's office where operating adjustments and maintenance may be more readily co-ordinated.

The "continuous" nature of the control stems from the smooth continuous motion of the differential Selsyn and bias motor, but the benefit of this, as compared with intermittent control is probably small, at least in hydroelectric generator control, because of governor damping. In any case "continuous" control probably breaks down at the governor, where the synchronizing motor is operated by contacts controlled by the governor Selsyn, and since there must be some clearance or dead band at these contacts, the synchronizing motor must operate in short pulses much as it would by intermittent control. The one great advantage of the governor Selsyn control is to ensure synchronizing motor travel proportional to the control signal, thus overcoming one of the difficulties in applying any kind of measured control to conventional governors.

Other characteristics of governors and turbines tend to handicap any type of automatic control unless specially dealt with. In particular there are:

1. Deadband in the governor due to friction, lap, slack linkages, and so forth.
2. Sluggish response due to dashpot damping.
3. Nonlinear power-gate characteristic.

However, these characteristics, which are difficult to eliminate, will be less detrimental to a relatively slow-acting control as described in this paper than to quicker-acting types.

Thomas W. Brown (Lombard Governor Corporation, Ashland, Mass.): The device described by Dimond and Lunge, in employing continuous comparison against a reliable standard, is unquestionably advantageous. In its employment of several relaying steps between the comparing unit and the turbine valves or gates, however, there may be hindrances to optimum performance. Recent work in a number of places, for example that of T. E. Curtis,[1] indicates that it is desirable for frequency comparison controllers to approach the rapidity of action of the "anticipation" type of control. In the authors' reference 17, it is stated that the telemetering system responds in less than one second; when to that fractional second time is added the lag of the governor speed control motor and that of the device, here described, for translating the receiver signals into a movement of the governor Selsyn, the over-all response time could become well over a second. This would establish a minimum dead band for rapidly changing system conditions, with the possibility of incorrect response if the changes are sufficiently rapid.

It would be of interest to know what is the range of the vacuum switch. If this is at all large, there must result a sort of step-response which would not help smoothness and continuity of action.

It would be of interest also to have a description of the device which accomplishes the time-correction function described by the authors. This would appear to be a separate unit feeding the bias motor jointly with the tie-line controller.

This paper significantly supports the argument that much can still be accomplished by a co-operative endeavor on the several parts of power system operating engineers, instrument designers, and governor builders, to produce an integrated and close-coupled regulating system specifically designed to fit the most desirable operating practices.

George S. Lunge: In his discussion of this paper, Duff states that because this system of frequency control perceives integrated deviation, rather than instantaneous deviation, from the standard frequency it must be incompatible with previously used automatic frequency control systems that respond to instantaneous deviations in frequency.

As in the case of earlier equipment (reference 1 of the paper) operating on the same basic integrated frequency-deviation principle, the authors see no reason why any difficulty should be experienced in interconnected operation if this type of frequency control is used on only one of the systems concerned, the remaining systems having automatic frequency control responding to instantaneous deviation in frequency, provided that comparable rates of correction are used on all of the systems involved. In fact, due to the smooth action of the control described, such interconnected operation should be accompanied by less severe tie-line power swings than those occurring when two systems, each having independent frequency control responding to instantaneous deviation in frequency, are interconnected.

The accumulated time deviation of one second from no load to full load has been quite generally used. It has been found that any drift in tie-line load due to difference between independent time standards is insignificant compared with tie-line load changes due to other causes, such as manual adjustment, discrepancies in governor performance, and so forth.

It is true that time bias cannot be introduced simultaneously with tie-line bias. It is customary to correct any accumulated time error daily at a time not likely to be inconvenient, such as shortly after midnight.

Although decentralized load-frequency control is inherently more expensive and less convenient to adjust than centralized control, it has the definite advantage of permitting independent control of operating areas in case tie lines trip out, and thereby reducing the time required to reestablish interconnected operation.

In reply to the point, mentioned by both Duff and Brown, regarding the intermittent action of the governor Selsyn unit, it should be noted that the system described is well suited also to direct Selsyn adjustment of the speed level setting of the governor, if the latter has a speed adjusting Selsyn with suitable gear ratio. The governor Selsyn unit is applicable to either steam turbines or hydraulic turbines; only the latter ordinarily have been provided with a speed level adjusting Selsyn as an optional feature.

Warren has called attention to the many points of similarity between the system described in his paper[1] and that described in the present paper. As pointed out by Bulkley, the frequency control portion of the equipment described in the paper has been in successful operation since 1939.

Brown's discussion emphasizes the need for rapid response in the telemetering system used with any automatic load control system and the advantage of eliminating further time lag in control by replacing the governor Selsyn unit (acting on the synchronizing motor) by direct Selsyn adjustment of the governor speed level, mentioned before as readily possible with this system.

The range of the vacuum switch in the governor Selsyn unit is mechanically adjustable. This is adjusted to a setting depending on the speed of the synchronizing motor and on the ratio of the feed-back gears.

As mentioned by Duff, the same motor is used both for tie-line bias purposes and for (occasional) time bias purposes. Since the two types of bias may at times call for opposite action, there would be nothing gained by using two separate motors for these functions.

IT IS quite fitting that the first electric shovel which the writer has been able to trace was shipped to the Milwaukee Railway and Light Company on July 5, 1902. This machine was built by the Vulcan Steam Shovel Company of Toledo, Ohio. It was equipped with a 1/2 cubic yard dipper, traction wheel mounting, and a boom-type front-end. Alexander Backus, then President of the Vulcan Company, was a personal friend of Thomas A. Edison and there seems to be no doubt that Mr. Edison was influential in persuading Mr. Backus to consider electric drive at that time. This shovel probably operated from a d-c trolley circuit.

A shovel presents a variety of problems to tax the ingenuity of the motor and control application engineer. The three main motions of a shovel, hoist, swing, and crowd, have entirely different characteristics. The hoist motion, which today is universally rope operated, pulls the dipper through the bank for loading, raises the load to the dumping position, and lowers the empty dipper for repeating the cycle. In addition to the usual problems in a mine hoist or skip hoist, a shovel hoist adds the design requirement of being able to stall under load without an interruption in power. The dipper teeth may strike an unyielding object, such as poorly blasted rock or an unforeseen boulder, but the motor must continue to pull even though stalled with the controller wide open.

The swing motion consists of rotating the machine about its center, moving the dipper back and forth between the digging area and the dumping position. The swing motion may be likened to a short-cycle transportation application, accelerating and decelerating a heavy mass. The crowd motion is auxiliary to the hoist in that it determines the depth of cut for digging, and the reach for dumping. The crowd also must be able to stall with the controller wide open without damage to the mechanical shovel or the electric equipment. Shovels today are mounted on crawlers, generally driven from the hoist motor.

This paper will cover what is usually known as the "three motor shovel" where each of the three main motions, hoist, swing, and crowd, are driven by an independent variable-speed motor. By contrast, Diesel power usually drives the three motions through clutches. Such machines may be driven also by a single-induction motor.

In the early days of building electric shovels, from 1902 to 1920, both a-c and d-c motors were used with rheostatic control. In the case of direct current, series wound motors were applied, and with alternating current, variable-speed wound-rotor induction motors were common. The first record of an a-c machine of this type is a four yard dipper dredge, very similar to a shovel, built in 1906. This machine had wound-rotor induction motors and was arranged to operate from a power supply of 2,080-volts 3-phase 25-cycle. It was shipped to H.R.H. Maharajah, Jammu, Kashmir, India, with two 18-inch hydraulic dredges. It is interesting to note that even at this early date, engineers appreciated the difficulty of ventilating a motor which was frequently stalled, and to solve the problem they used forced ventilation. Also the advantages of lower flywheel effect resulting from using twin half-sized hoist motors, a common practice today on larger machines, was appreciated at that time.

Prior to 1920 there existed in the electric shovel industry a battle between alternating and direct currents, very much the same as existed on the question of railroad electrification. Since most power supply was alternating current, the d-c motor shovel required a motor-generator set. The a-c shovel usually was driven by 440-volt motors with transformers on board, to step down from 4,000 or 2,300 volts.

Today the 3-motor shovel is offered in sizes two cubic yards and larger. Four cubic yards and smaller shovels are available also as friction-type machines driven by Diesel or gasoline engines or single electric motors. Draglines with variable-speed motors on the several motions are available in $2^1/_2$ cubic yards and larger sizes, and in sizes ten cubic yards and smaller are available with Diesel-drive. The smaller sizes are sold with gasoline engines and single electric motors.

The first Ward-Leonard electric shovel was put into operation in 1920. It might be added that the term "Ward-Leonard" in the shovel industry refers to a d-c motor driven by its own individual generator, whereby the torque and speed of the motor are determined by controlling the field of the generator. This type control is sometimes referred to as "variable voltage control." One of the principal advantages which this type control offered was a more effective and permanently adjusted means of causing the motor to stall down and continue to pull at a predetermined maximum torque without interrupting the circuit. The steam engine had accomplished this result in a most excellent manner due to its limited boiler pressure. With the earlier rheostatic control using both alternating and direct current, the stalling torque was limited, after a fashion, by using "notch back" or "jamming" relays. Such devices were not fully reliable, however, on account of

Paper 48-269, recommended by the AIEE mining and metal industry committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted August 9, 1948; made available for printing September 13, 1948.

P. S. STEVENS is with the Bucyrus-Erie Company, South Milwaukee, Wis.

wear and tear, and lack of understanding on the part of operating personnel in the early days of electric shovels.

Differential Series Field

With the Ward-Leonard control, the stalling torque limitation was obtained by using a differential series field on the generator. It gave to the electric motor the steam engine characteristic in a foolproof fashion, and with means which would remain reasonably permanent in adjustment. Differential compound generators were used and their drooping voltage is well known in comparison with the flat compound and shunt generator characteristics. The drooping voltage with increasing current causes the shovel motor to stall down and still continue to pull hard without abusing itself or the mechanical parts of the shovel.

The earlier Ward-Leonard electric shovels were equipped with series motors, a carry-over from the rheostatic control. The series motor is an excellent tool for digging and hoisting, but it is not so effective for braking operation or lowering the dipper. However, after considerable experimenting, the series motor was made to lower the dipper reasonably well, and in spite of its shortcomings, some of the original Ward-Leonard series motor machines are still in operation. For instance, I had the pleasure this year of seeing in operation in a coal mine in Ohio, a series motor equipped Ward-Leonard machine which I witnessed begin its life on the Iron Range in northern Minnesota in 1920. The old machine is still doing a creditable job.

Three Field Generator

The next important development had to do with the generator. The original shovel generator was made with two fields, one separately excited shunt-type field which was varied for motor speed control, and a differential series field with a fixed number of turns. The usual commutating fields of course were used. The objection to this characteristic was that when the motor began to pull hard, the voltage of the generator was too low and the digging speed entirely too slow. The corresponding steam shovels would dig much faster. The problem was put up to the generator designer who solved it by adding a third field, a self-excited shunt field which raised the voltage characteristic effectively especially at operating loads. This change gave the shovel the well known "3-field generator."

The first Ward-Leonard shovel had a no-load generator voltage of about 330 applied to a 230-volt motor. The self-excited field increased the no-load voltage to about 400. Over the years, generator and motor designs have improved so that no-load voltages of 575 volts are common in shovel equipment. This has resulted in faster operating speeds without increased sizes of motors. In the shovel industry, we use for Ward-Leonard equipment specification purposes, the continuous horsepower rating of the motor at 230 volts. Actually in service the generators develop approximately 460 volts at the motor continuous current. Hence, if anyone attempts to compare the horsepower of a Ward-Leonard shovel with a Diesel-driven shovel for example, he should increase the electric motor continuous rated horsepower by 100 per cent before comparing with the horsepower of a Diesel engine on a similar size shovel. The same increase must be made before comparing with some applications of a-c motors to shovels and dredges.

Referring again to the series wound motors and analyzing the characteristics brings out several objections. The heavy armature circuits had to be opened for reversing, and this required large contactors. The control when plugging or lowering the dipper was rough on commutators. To accomplish reasonable operation required a variable generator differential field, armature resistors, armature contactors and generator self-excited field contactors to insure reduced generator voltage before opening the armature circuit. The operation timing of these devices was determined by rotation direction switches on the machinery shafts. The result was a considerable layout of what would be termed today "gadgets." In shovel operation, with its relatively short cycles, lowering, braking and deceleration rank closer in importance to acceleration and pulling than in many other applications hence attention was turned to the shunt motor which can hold back as readily as it can pull.

Shunt Motor

A shunt-type motor with a separately excited field has not as much peak torque per ampere as a series motor. However, the proper size of motor to drive a shovel motion is not determined by the motor's peak capacity. It may seem strange to many of you that the proper size of motor is determined by its continuous load carrying thermal capacity. Shovel motors in most cases are forced ventilated to improve the continuous rating, and with such have more than ample peak or stall capacity with separately excited fields for shovel operation. Hence, the separately excited or shunt-type motor offered excellent possibilities for simplifying shovel control as well as greatly improving operating characteristics.

With the separately excited motor, reverse rotation is obtained by reversing the generator separately excited field. Negative torques are handled just as readily as positive torques and without gadgets. High-speed empty dipper lowering is accomplished by raising the generator voltage to a maximum, and weakening the motor field somewhat. Plugging for stopping is smooth and trouble-free. Control became simplicity in the extreme. Motor and generator armatures were connected solidly with no resistors, contactors, or knife switches.

The first completely shunt motor equipped shovel was put into operation in 1925 as a seven cubic yard coal loading machine for a stripping mine in Montana. The advantages of the shunt motor were realized immediately by operating people as well as designers, and while for several years there were still arguments about whether series motors or shunt motors were better, in 1928 the shunt motor became universal. The considerable regeneration of power when lowering the dipper or stopping the swing motion was sufficient to require a 15 to 20 per cent downward revision of kilowatt hours per cubic yard excavated. It might be interesting to know that the large electric stripping shovel today equipped with balanced hoist, which will be discussed later, will dig and move a cubic yard for 0.3 of a kilowatt hour. Draglines are not so efficient as will be pointed out later.

An early typical installation of Ward-Leonard control with shunt motors and three field generators is shown in Figure 1 with schematic diagram and a tabulation of individual field adjustments for each point on the controller. This form was very effective in training field erecting and operating personnel. In the early days a shovel motion would be reported as slow and an inspection by a factory engineer would disclose that the self-excited generator field was not connected. Such experiences were eliminated by calling for definite voltage readings by the erector on the self field connected alone as called for on this form.

Motor Lowering of the Dipper

It was the practice with early railroad-type steam shovels to lower the dipper by declutching the engine and catching the falling dipper on a mechanical brake.

Figure 1. Early shunt motor control with schematic diagram and field adjustments

On larger steam stripping shovels appearing later, it was the practice to back the dipper down part way on the engine using a release throttle, and then after nearing the digging position throw out the clutch and lower the remaining distance on the brake.

The first a-c stripping shovels, six to eight cubic yards, put into operation in 1917, accomplished the complete lowering cycle of the empty dipper by means of the motors. The hoist machinery, however, was equipped with clutches and brakes as for steam operation. The early rheostatic d-c stripping shovels lowered somewhat after the fashion of the steam shovel, part way on the motor and part way on the brake. At that time all smaller electric shovels lowered completely on the brake.

Figure 2 is a kilowatt input chart of one of the earlier a-c stripping shovels using motor lowering. The chart reads from right to left and shows to the right of point "A" a regenerating portion of the cycle below the zero line; then follows, before digging, the high peak required to stop the motors from reverse synchronous speed and accelerate them to forward hoisting speed. This particular chart was made of a shovel loading cars at high lift, and shows quite a long hoisting cycle after the rugged digging portion. The peak load to the left of dumping is hoisting the empty dipper out of the car so that the open door clears the side of the car, and the kick-off power to accelerate the motors in the downward direction before regeneration begins.

Up to 1925 no attempt had been made to lower the dipper of a close-coupled fast-cycle shovel on the motor. However, Ward-Leonard control with the shunt motor offered new possibilities. Heretofore, all electric shovels were in reality electrified steam shovels. The first real electric shovel was designed in 1925, and the hoist machinery was equipped with only a small disconnecting clutch so the motor could be used for propelling. It was not equipped with a large size brake suitable for lowering the dipper. The design contemplated motor lowering. This was the first four cubic yard full revolving shovel which replaced the old heavy-duty fast-cycle railroad-type shovel common in this country.

The first demonstration of the motor lowering feature of this shovel was rather disappointing to many, because it was so smooth it appeared slow. It was not as spectacular as dropping a dipper and catching it on a brake. The opponents lost account of the fact that often the brake lowered dipper would be carried in a high position during a considerable portion of the return swinging cycle, and then dropped fast to make up for lost time. With motor lowering it was only necessary to begin the lowering stroke immediately after dumping the load into the car, and even at a reduced top speed, compared to gravity falling, the dipper would be down as fast as the swing was over to the digging position. Motor lowering is much easier on the operator because he accomplishes the complete hoisting and lowering operation with the controller handle, and he is relieved of foot brake and clutch operation. It is also easier on the machinery, hoist rope, and entire shovel. Motor lowering has become, even on the smallest Ward-Leonard shovels, practically universal today.

Figure 3 shows the kilowatt input to a Ward Leonard hoist on an eight cubic yard shovel with motor lowering. The cycle shows clearly the digging, hoisting, dumping, and lowering operation. The high peak regeneration at the end of the lowering strike is due to stopping the motors at the bottom of the pit. It will be noted that the amount of regeneration with the Ward-Leonard is considerably more than in the case of the a-c shovel because regeneration with the Ward-

Figure 5. Five cubic yard quarry and mining-type shovel loading cement rock

Leonard takes place right down to standstill, whereas with alternating current, regeneration takes place only when running above synchronous lowering speed.

New Motor with Reduced Flywheel Effect

Shunt motor Ward-Leonard control was such an improvement in permitting fast and smooth plugging that it focused attention on the fact that the shovel cycle could be improved if motors with reduced flywheel effect were available. In the early days, electric shovels were properly classed as slow in comparison with steam shovels, because it required too much time to accelerate and decelerate the motor armature. The steam engine accelerated to speed almost instantly.

The first hoist motor on the newly developed four cubic yard electric shovel of 1925 had a WR^2 of 1,040 pound-feet squared. It could make four cycles per minute hoisting and lowering the empty dipper which is a good measure of the effectiveness of motor lowering. The first model of a new line of motors developed shortly thereafter had a WR^2 of 437, and permitted five cycles per minute of the hoist motion. A kilowatt chart of this operation is shown in Figure 4. The normal complete cycle of such a shovel including digging, swinging, dumping, and return is three cycles per minute in good digging. In rock the speed is two cycles per minute.

Figure 5 shows a five cubic yard shovel in a cement plant quarry loading trucks.

Figure 6 shows the revolutions-per-minute of a shovel motor on the hoist motion clearly indicating the high rpm used in lowering the dipper. This chart was taken by a recording mechanical tachometer which did not distinguish between positive and negative rotation.

A third line of motors known as the new *600 Series*, is now available for shovel operation. A comparison of the three lines is shown in Table I covering the size used on the original four cubic yard hoist in 1925, and a five cubic yard hoist today. The 1925 shovel grew to five cubic yards several years ago.

Each motor is smaller physically than its predecessor, a valuable improvement for a compact shovel layout.

The Balanced Hoist

The next major improvement made in electric shovels and closely related with shunt motor Ward-Leonard control was the balanced hoist used for the first time in 1930 on a 16 cubic yard stripping shovel. The separately excited motor having the characteristic of continuing to run at about the same speed even if the torque load is reversed from negative to positive permits the effective use of a movable counterweight to help hoist the dipper. The arrangement of such mechanism is shown schematically in Figure 7. Such shovels have heavy ballast at the rear for stability, and to use some of this ballast as live counterweight does not add to the total weight of the machine. The advantages of counterweights are well known in elevators and hoists. A counterweight permits the use of a smaller size motor to do the same work and greatly improves the safety condition in case of power or brake failure. On a shovel, however, there are other advantages not found in the elevator or hoist.

For example in the "lowering" section of Figure 7, the balancing point between empty dipper and live counterweight occurs when the bail pull reduces to 45,000 pounds. It is easily understood how the bail pull reduces as the dipper lowers, because when the dipper handle reaches a vertical position, the pull on the hoist rope is zero as the entire dipper and handle weight are then supported by the shipper shaft. This means that below the balancing point, the hoist motors must lift the counterweight to permit the dipper to continue in its lowering direction. Tracing through the lowering operation, the hoist motor controller handle is thrown into reverse direction after dumping, and there is an input kick-off, during which period the motors are motoring to accelerate themselves until the weight of the falling dipper overhauls them and the motors begin to regenerate and hold back.

Figure 6. Motor speed during normal digging cycles, showing high-speed motor lowering with Ward-Leonard control

Table I

	Frame	WR^2 Pounds Feet	Horsepower Continuous Rating, Unblown.	Horsepower Continuous Rating, Blown.
Original motor	109	1,040	140	
Improved motor, 1926	418	437	150	187½
New motor, 1948	616	365	150	187½

The effect of the falling dipper weight is high at the beginning of the stroke, and combined with the electric power input accelerate the motors quickly. At the bottom portion of the lowering stroke, the bail pull is reduced to such an extent that the effect of the counterweight is then used in addition to electric power to stop the motors. The controller handle is thrown into the hoisting direction before the motors reach the bottom of the stroke. The result is that the counterweight and electric power stop the motors quickly at the bottom and accelerate them again into the hoisting direction. The effect of this is just the same as if a subway train were permitted to run downhill when leaving a station during acceleration in order to reach a high speed quickly, and then run uphill during deceleration to stop quickly at the next station.

The reduction in both motor size and power demand with the counterweight is self-evident. Also the kilowatts drawn from the line are less and the kilowatts pumped back into the line are less, because the counterweight has the effect of reducing both. The spread between positive and negative power peaks is reduced.

There is still another advantage of the counterweight in connection with the electric power use. This comes about from the fact that some power companies that

Figure 7. Shovel with balanced hoist shown schematically digging and lowering empty dipper

Figure 8. Speed-pull curve of large shovel hoist comparing large motors without balanced hoist and small motors with balanced hoist

have shovels and draglines on their lines install, I think unfairly, ratchets on their kilowatt-hour meters. During periods of regeneration, of course, the shovel tends to drive the kilowatt-hour meter backward and unwinds some of the power recorded previously. Ratchets prevent this. These large stripping shovels operate three shifts per day whereas coal is usually loaded out of the mine during only one shift. During the day shift, of course, there is enough other load on the line inside the meter to absorb the regenerated power from the stripping shovel, but during the night shifts this is not usually the case. Hence the energy shown by the kilowatt-hour meter for large stripping shovels, with or without a counterweight, is greater than the energy actually used on a net basis. The difference between actual and recorded energy is less with a balanced hoist shovel, because the balanced hoist stores up a certain amount of the energy during the lowering of the dipper and gives it up during the digging. This is another reason why a balanced hoist shovel has a lower power bill, and is in addition to the

Figure 9. Large stripping shovel with balanced hoist stripping bituminous coal

fact that its motors being smaller to begin with use less power.

Another advantage is faster acceleration resulting from smaller motors.

A comparison of flywheel energy of motor armatures typical of those used on 35- and 40-yard shovels today is helpful. The 425-horsepower motor is used without a counterweight, and the 250-horsepower motor with a counterweight, two of each driving the hoist motion. The relative figures for one well-known make of motor are shown in Table II.

The older 250-horsepower motor shows a considerable advantage in flywheel effect, but the new 250-horsepower motor available today is still better as indicated by the figures. This explains why shovel runners notice that the smaller motors start and stop quicker, resulting in a faster digging cycle.

A comparison of bail-pull and bail-speed figures of two 425-hp motors without balanced hoist and two 250-hp motors with balanced hoist shows that the two can be made to do the same work and the smaller motors have the advantage of faster acceleration, reduced power consumption, and reduced heating. In Figure 8 the continuous rating of the 425-horsepower motor without balanced hoist occurs at a lower bail pull than in the case of the smaller motor. That is to say, a greater percentage of the cycle with the large motors exceeds the continuous rating.

It is true that the counterweight carries a rope maintenance item, but estimates

Table II

Motor Frame	Horsepower Continuous	WR^2	Continuous Rating, Rpm	Maximum Safe, Rpm	$WR^2 \times$ Continuous Rpm²	$WR^2 \times$ Maximum Rpm²
422	425	1,800	375	1,250	253 $\times 10^6$	2,820 $\times 10^6$
420	250	800	400	1,400	128 $\times 10^6$	1,578 $\times 10^6$
618	250	580	410	1,500	97.5 $\times 10^6$	1,300 $\times 10^6$

Figure 10. Large dragline stripping iron ore in Minnesota, and loading a belt conveyor through a mobile hopper

Figure 11. Large dragline machinery with independent motors on drag and hoist

show that this is less than the cost of the extra power with the larger motors. Figure 9 shows a large shovel with balanced hoist stripping coal.

The balanced hoist is available only on the larger stripping shovels. The smaller quarry and mining type machines do not have enough space to permit such an installation.

Large Ward-Leonard Draglines

The advantages of Ward-Leonard control are not confined to the shovel. They are also effective on the dragline excavator. With a dragline the digging bucket is suspended on two ropes, the drag rope which does the digging, and the hoist rope which does the lifting after the bucket is filled. A dragline stands above its work and digs below itself, sometimes being used to excavate under water. In contrast to this a shovel digs above itself. A dragline has the advantage of longer reach and has in recent years become very popular for coal stripping where properties with shallow overburden are becoming scarcer. Deeper stripping is being considered today in the order of 75 feet or more cover above a vein of coal. As draglines become larger, the conventional method of handling the bucket by driving the drag and hoist drums with one motor and using clutches and brakes becomes more of a problem.

During 1942, the first dragline with individual motors on the drag and hoist drums was put into operation with a 25 cubic yard bucket in an Illinois coal strip mine. This eliminated the need for using brakes and clutches, and while such a drive is quite expensive, the benefits are so great that the trend has now spread to smaller machines, even down to the eight cubic yard size.

Figure 10 shows a 25 cubic yard dragline with individual motors stripping iron ore in Minnesota. Large draglines are widely used in the anthracite field where there is much rock digging and such draglines perform exceptionally well in this service. Years ago a dragline was not considered a good rock digging tool, but Ward-Leonard control and individual motor drive have helped make these large machines economical in rock work.

These machines handle 25 cubic yard buckets on 180-foot booms and swing on a 34 foot diameter roller circle. Such a machine of course is shipped knocked down and consists of 47 freight car loads. The working weight is approximately 2,500,000 pounds including 275,000 pounds of ballast in the rear of the revolving frame. It is equipped with walking-traction mounting instead of crawlers as commonly used on shovels. It is driven by two-motor-generator sets and d-c motors as shown in Table IV. Figure 11 shows the machinery layout of a large dragline.

A dragline of this size will draw peak loads of 2,600 kw and pump back to the line peaks of about 1,300 kw. The energy consumption, in kilowatt-hours per cubic yard excavated, is 50 to 75 per cent greater than that of the large shovels equipped with balanced hoists. The dragline usually moves the material farther and lifts it higher than the shovel and considerably more electric equipment with attendant losses is required for the dragline to handle the same yardage.

The dragline does not lend itself well to the benefits of a live counterweight. On a shovel, one motion digs and hoists and one counterweight assists both operations, whereas on the dragline, two counterweights would be required with resulting complication. Furthermore, the dragline ropes travel farther than the shovel ropes so that either excessively high counterweight towers would be required, or one must accept higher friction losses and counterweight rope wear by using more parts of line and more sheaves with short towers.

An alternate power peak absorbing arrangement as used in large steel mill drives and mine hoists, consisting of flywheels in the motor-generator sets, has not yet seemed justified.

Table III. Comparison of Shovel Dipper Power With and Without Balanced Hoist

Motors	2—425 Horsepower Without Balanced Hoist	2—250 Horsepower With Balanced Hoist
Stalling Bail Pull, Pounds		
By motors	375,000	275,000
By counterweight		100,000
Total	375,000	375,000
Maximum Safe Lowering Speed		
Motor—rpm	1,250	1,500
Dipper bail—fpm	440	437
Continuous Motor Rating Bail Pull, Pounds		
By motors	171,000	119,700
By counterweight		100,000
Total	171,000	219,700

Temperature Compensation

The early Ward-Leonard equipment on shovels and draglines experienced an excess of bail pull and motor torque when starting up cold in the wintertime. This came about because at low temperatures, field resistances were low and excitation above normal on the exciter, generator, and motor. After the equipment had been running for several hours and was up to temperature, motor torques would become normal. In northern climates this differential was a considerable item, and combined with it was the fact that most steels are weaker at low temperatures, and should not be subjected to higher than normal stresses. In some localities, greater than normal dipper handle maintenance was experienced in the wintertime.

This problem was well considered by operators, shovel manufacturers, and electric equipment manufacturers, and today equipments are provided with special characteristics which maintain approximately the same motor torques at

Table IV. Electrical Equipment of 25 Cubic Yard Dragline

Motor-Generator Sets	
Hoist and drag	1—1,250 horsepower synchronous
Swing and exciter	1—500 horsepower induction
D-C Motors	
Hoist motor	2—425 horsepower continuous
Drag motors	2—423 horsepower continuous
Swing motors	3—125 horsepower continuous

various temperatures. For example, starting up on a cold morning, exciter voltages are below the normal of 125 volts.

One scheme of accomplishing this result is to use a high resistance differential shunt field in the constant voltage exciter. Another scheme is to use thermal magnetic shunts between the main pole tips in the constant voltage exciter. Both schemes are effective.

Rotating Control

Large draglines and large shovels are equipped today with what may generally be termed "rotating control" in connection with the Ward-Leonard application. Commonly used on excavators are the General Electric Company "Amplidyne" and the Westinghouse Electric Corporation "Rototrol". Rotating control adds a variable voltage exciter, in fact, a small motor-generator set to each of the hoist, swing and crowd motions in addition to the constant voltage exciter, which is common to all motions. These rotating control units replace the bulk of the contactors and part of the field resistors required with the magnetic-type control used on the smaller machines. Rotating control produces a faster response of the generators to the needs of the operator for quick changes in power, with the result of an appreciable gain in output. The advantages, however, do not seem to justify the extra cost on shovels smaller than five or six cubic yards, and draglines smaller than eight cubic yards.

This brings us up to date on the subject of Ward-Leonard control for electric excavators, and in closing I am tempted to forecast the future trends which, of course, is a dangerous pastime. However, there does not seem to be any other scheme of power transmission on the horizon which is as well suited to the requirements of shovel and dragline operation as the modern Ward-Leonard electric control. The nearest approach today is the hydraulic transmission with variable stroke pumps, the "Oilgear", being a good example. However, such equipment is not yet developed in large enough units, and even in the small sizes available today, it is still too costly, in comparison with Ward-Leonard equipment, to be used commercially on shovels.

High pressure steam and enclosed circuit compressed air systems have been proposed, but the shovel industry has not been large enough to carry on such pioneering work itself. The trends in locomotive development include electric transmission with steam and gas turbine drives as well as with Diesel engines; hence the shovel industry does not expect much help from this quarter as far as transmission of power from a constantly rotating prime mover to the shovel dipper is concerned.

For contracting work, the clutch-type machine driven by internal combustion engines is preferred because of its independence of power lines. No doubt when higher-speed more compact Diesel engines are available, Diesel drive will be used on larger machines, combined probably with Ward-Leonard transmission. The friction driven machine is gaining ground in the smaller sizes, as evidenced by the fact that before 1930 Ward-Leonard electric shovels were sold in sizes as small as $1^1/_2$ cubic yard capacity, whereas today there are very few machines sold smaller than $2^1/_2$ cubic yard capacity.

It seems quite certain that any form of power transmission which is to replace the Ward-Leonard drive for large machines in the future must provide for power braking, as it has been a great relief to both user and manufacturer to be free of the problems connected with large heavy duty mechanical brakes and clutches. Ward-Leonard control with its regenerative braking characteristic has done the job so well that it seems to be safely entrenched for some years to come.

MEMBER AIEE

THE rapid mechanization of all industry is perhaps nowhere better typified than in the mining of basic raw materials from the earth. These raw materials, coal, metals, minerals, and construction materials, occur either at places on or near the surface of the earth, or deep within the earth.

This paper is primarily concerned with surface excavating apparatus that is predominant in the production of these raw materials. Power shovels and draglines today handle more tons of earth and its mineral products than any other form of earth-moving apparatus, and last year they moved close to five billion tons of material, or about 70 per cent of all material handled. This included approximately 78 per cent of the three billion tons of coal, iron, copper, lead, zinc, and other metals and minerals mined, including earth moved prior to mining, approximately 95 per cent of the 650 million tons of construction materials, sand, gravel, stone, and clay produced, and approximately 60 per cent of the two and one-half to three billion tons of earth moved in construction operations. An idea of the magnitude of raw materials production today can be obtained by comparing these tonnages with a well known excavation like the Panama Canal, whose development through 1920 amounted to about 400 million tons.

Description of a Shovel

A power shovel or dragline is a production tool whose output is measured in terms of the amount of material that can be handled, the distance the material can be moved, and the time consumed in normal operation. The physical size of a machine is determined by these factors, and is usually identified in terms of dipper or bucket capacity in cubic yards and reach or boom length in feet. For a given machine these dimensions may vary with weight per cubic yard of material being handled. The larger shovels and draglines are the largest mobile production tools in use today.

A modern power shovel consists essentially of six parts. A typical large stripping shovel is illustrated by Figure 1. The dipper handles the material by a scooping action from the hoist motion into the open end of the dipper and subsequent discharge through the opposite or door end. The scooping is augmented by teeth set along the lower open lip. The discharge door is tripped to unload the material at the will of the shovel operator. The dipper stick mounts the dipper and causes its extension into or withdrawal from the work due to effort from the shovel crowd or thrust motion. The boom usually mounts the dipper stick and often the crowd machinery and extends further out into space to mount a sheave over which the hoist rope passes to lift the dipper. The length of the boom determines the reach of the shovel. The shovel shown in Figure 1 has a slightly different crowd motion arrangement to perform the same function. The upper frame carries the lower end of the boom and, by suitable supporting and bracing, fixes the boom position in space so that the boom and upper frame are integral. The upper frame is covered and mounts the hoist, swing, and power conversion or engine machinery, and occasionally the crowd machinery. The upper frame is rotated about a center pintle on rollers on a circular track by the swing motion. The lower frame supports the swing circle and hence the complete shovel. The lower frame is supported by caterpillars and the propel motion is accomplished by suitable machinery at the caterpillars or by mechanical connection to one of the main shovel motions.

Description of a Dragline

A modern power dragline consists essentially of the same parts as a shovel, with a few exceptions. A typical large stripping dragline is illustrated by Figure 2. The bucket handles the material by a scooping action from the drag motion, the material being subsequently discharged out the same open end of the bucket by a tipping action from the hoist motion. The front or open end of the bucket is equipped with teeth along the bottom lip to augment scooping, and the attitude of these teeth to the work is maintained by the hoist motion to control the amount of scooping. A dragline has no dipper stick or crowd motion. The boom can then be much longer than that on a shovel. The upper frame mounts the boom and main machinery, as on a shovel, and similarly, rotates on a swing motion circle. The lower frame carries the dragline weight and may be supported by caterpillars or a flat tub. If equipped with caterpillars, the propel motion is similar to that of a shovel. If the dragline is of the walking type, the propel motion serves to lift and move the lower frame tub by means of large outboard shoes hung from and actuated by machinery in the upper frame.

Shovel and Dragline Application

Excavators are applied to a given job as a function of the daily or monthly output requirements, the type and structure

Paper 48-270, recommended by the AIEE mining and metal industry committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted August 4, 1948; made available for printing September 8, 1948.

of the material to be produced or moved, whether the material is to be loaded in haulage equipment or merely displaced, and the range or economic duration of the job. These factors with minor variations influence the selection by the user and his choice between shovel and dragline. This paper does not intend to cover this field. However, a general utility tabulation by shovel and dragline dipper or bucket size is shown for illustrative purposes in Table I. Note the predominant production part played by large stripping shovels and draglines, accounting for their prestige in the industry.

Shovel Motion Requirements

The hoist motion speed-torque requirements are indicated in Figure 3(a). High torque, adjustable by the operator to meet the load demand, with a definite maximum limit, is required from slow through intermediate speeds, with high torque available for acceleration, deceleration, and reversing. The system must withstand heavy shock loading. High speed, adjustable by the operator, must be obtained for low-torque requirements. When lowering, speed should be even greater for economy of time, as indicated in Figure 3(b), since torque requirements are lower.

The crowd motion speed-torque requirements are similar to those for the hoist, as in Figure 3(a), with both speed and torque adjustable. The crowd system must also withstand heavy shock loading. Speed changing, however, is not required between the two directions of motion.

The swing motion speed-torque requirements are indicated in Figure 3(c). Again adjustable torque is required, with high torques available for acceleration, deceleration, and reversal. However, the rate of application of torque to the drive should be low enough so that the high inertia swing system will not experience excessive mechanical stress in its parts. The low-torque speeds should be as high as possible for coasting.

The propel motion speed-torque characteristics should be similar to those shown in Figure 3(a). The main requirements are adjustable torque for starting, with high maximum torque available, and constant speed running.

Dragline Motion Requirements

The drag motion on a dragline is essentially the work motion. The drag speed-torque requirements are shown in Figure 3(a), as for a shovel hoist, with both speed and torque adjustable. Again this system must have high shock load capacity. For economy of time when paying out the drag rope, speed should be increased over the drag speed, as in Figure 3(b).

The hoist motion on a dragline is more of an accessory to the drag motion. Therefore, particularly when dragging up a bank, the hoist motion speed-torque characteristics should have steep slopes so that the hoist will tend to automatically follow the drag to facilitate even, consistent loading of the bucket. The requirements are therefore as shown in Figure 3(c), with adjustable high torques and steep slopes. For economy of time when lowering, the speed should be increased over the hoisting speed, as in Figure 3(d).

The swing motion requirements are as shown in Figure 3(c), with adjustable torque and high-speed coasting. As for a shovel swing, emphasis is on smooth, even application of high torque for acceleration and deceleration.

The propel motion requirements are again the same as indicated in Figure 3(a), with adjustable torque for starting and

constant speed running. Very often the propel drive is common to one of the main motions, so that mechanical means provide necessary lower speeds and higher torques than are normal for that main motion.

Power Drives for Shovel and Dragline Motions

The power drives employed on shovels and draglines to achieve the functional motion requirements have evolved with growth of the industry from steam to the modern d-c Ward Leonard drive with generator field control. Early attempts at electrification were aimed at reproducing the characteristics of the steam drive. Later efforts have improved on them by obtaining far greater digging ability, more protection for machine and personnel, lower operating costs and maintenance.

Two different systems of generator field control for electric d-c Ward Leonard drives are used today. They are known to the trade and will herein be referred to as the magnetic type employing contactors or other magnetic switching devices to adjust the generator field, and the rotating type, employing a separate exciter for supplying and adjusting the generator field.

An evaluation of the requirements for best performance from a motion drive is shown in Table II, comparing earlier with modern systems. Speed-torque requirements for best motion performance already have been indicated in Figure 3. Speed-torque characteristics available from the six systems, shown in Figure 4, are compared on an equal horsepower and maximum torque basis, except that the clutch and electric a-c rheostatic drives require considerably higher pull-out torques.

Table II. Comparison of Various Motion Power Drives

Requirements for Best Performance	Steam	Clutch	Electric-A-C (Rheostatic Control)	Electric-D-C (Rheostatic Control)	Electric-D-C Ward Leonard, (Magnetic Control)	Electric-D-C Ward Leonard, (Rotating Control)
High power capacity	Low	Low	Fair	Fair	High	High

Low maintenance of machinery and control	High	High	High	Fair	Low	Low

Steam Drives

The steam drive was considered good because high torque was available at low speed, and the drive speed was high for low-torque requirements. The steam engine had low inertia for rapid speed changes, and was simple, sturdy, and rugged. However, the steam drive lacked high peak power output. Power efficiency was low, with problems attendant to coal and water supply. Speed braking was provided. Space and weight requirements were excessive and maintenance high. Because of these many disadvantages, steam drives have been universally superseded by electric and internal combustion engine drives.

Figure 3. Speed-torque requirements for shovel and dragline motions

Figure 4. Speed-torque characteristics available from various types of shovel and dragline power drives

Clutch Drives

The clutch drive is simple, inexpensive, has low inertia for rapid speed changes, and space and weight requirements are low. However, the clutch drive power characteristics are dependent on those of its prime mover. To obtain high-torque output comparable to other systems, the prime mover must have much higher maximum torque. To obtain comparable high speed for a low-torque requirement, the prime mover must be oversize in power rating. The clutch drive is used primarily on small shovels and draglines driven by gas and Diesel engines or a-c motors. On some medium sized draglines, this type of drive is still used because it provides low inertia, high-speed lowering of the hoist or high-speed payout of the drag motions. Maintenance is high enough to discourage usage on the larger excavators.

Magnetic couplings are used on some small and medium shovels and draglines to overcome the maintenance due to wear on usual clutch friction surfaces. This drive provides smooth, adjustable torque control with definite torque limit. By special treatment, adjustable speed control is possible. Like electric a-c rheostatic drives, the magnetic coupling has high-speed low-torque limitations. Clean release, low inertia, and heat dissipating capacity should be provided.

Electric A-C Rheostatic Drives

The electric a-c rheostatic drive (wound rotor motor) was simple and stable and

provided fairly good accelerating torque control, but required load limiting relays. Space and weight requirements were fairly low. However, high-speed low-torque operation could not be obtained without the use of oversize motors. Speed control was poor, with no automatic speed changing, and good motion co-ordination was difficult to obtain. Power efficiency was low. Machine inertia was high. Maintenance was high due to difficulties in producing sturdy designs. This drive was one of the first attempts to simulate basic steam engine characteristics electrically, but is obsolete today.

Electric D-C Rheostatic Drives

The electric d-c rheostatic drive provides fairly good torque control, high light-load speeds, and automatic speed changing. Machine inertia is low and mechanical construction is sturdy to afford low maintenance. Space and weight requirements are low. However, power efficiency is also fairly low and no positive speed control is provided, resulting in poor motion co-ordination. Of the early attempts to electrify drives, this type offered the closest to steam characteristics. Where inexpensive, very small drives are required, this type is still used today.

Electric D-C Ward Leonard Drives

The electric d-c Ward Leonard drive with magnetic generator field control affords high peak-power at high speed from low thermal machine ratings. In ability to handle shock loading, the drive is second only to the steam engine. Power efficiency is higher than in other systems, considering very little full-speed operation in a cycle. Good, adjustable torque control is provided, with adjustable regenerative braking. Counter-torque braking is not required. Automatic speed changing is accomplished by steep generator characteristics and motor field weakening. Power characteristics are made stable with respect to temperature variations. Machine design is sturdy and simple and motor inertia is low, providing low space and weight requirements and low maintenance. Even though adjustment of light-load speed over a wide range is lacking with magnetic generator field control, the drive can be used to power even the largest shovels and draglines. Very good operating results are obtained under the severest of duty requirements. Today the drive is used extensively, particularly on smaller shovels and draglines where the refinements and special operating characteristics of rotating generator field control are not economically warranted. The drive is also used quite often for the swing motion only on smaller clutch drive machines.

The electric d-c Ward Leonard drive with rotating generator field control affords all of the foregoing advantages plus very flexible adjustments of speed and torque control. Adjustable rate of application of torque (dynamic response) is afforded. This control can be designed to fulfill the speed-torque requirements for any shovel or dragline motion for proper co-ordination of motion controls and minimum operator fatigue. This type of drive with rotating generator field control is now standard on all large shovels and draglines.

Components of Typical Electric D-C Ward Leonard Drive

This shovel or dragline power drive system is of the adjustable d-c voltage type, comprised essentially of a d-c motion-driving motor which receives power at adjustable voltage from a d-c generator. The generator is driven at constant speed by and receives power from an a-c motor or occasionally an engine. Generator field excitation is derived from a constant voltage source and is adjusted by the control circuits. On larger excavators several drive motors per motion may be required, each receiving power from its own d-c generator.

D-C Driving Motors

D-c driving motors are built for extra-heavy-duty service to withstand severe mechanical strains, variable voltages, and heavy currents. They are the same rugged motors used so successfully in steel mills for auxiliary and crane service. Heavy steel frames are split and the top half hinged for ease of inspection in typical motors. Mounting dimensions are standardized throughout the industry. Large roller bearings on horizontal motors and large ball bearings on vertical swing motors are mounted in dust-tight, removable, keyed frame heads to carry the heavy shock loading. Therefore, armatures can be removed easily without exposing bearings to dust and dirt. Armatures are especially designed for low inertia and high speed operation. Long life brushes, extra large commutators, and high insulation levels provide extra overload capacity. These protected motors are provided with high-temperature, class "B" insulation with inorganic, silicone-type binders, and are separately forced ventilated to obtain the highest power capacity for low space and weight requirements. Motor driven blowers are usually integrally mounted. Some progress has been made toward a filtered air supply common to several motors. A complete line of these 230-volt d-c, shunt wound, blown, 75 centigrade rise continuous motors is available, ranging in size from $12^1/_2$ horsepower at 775 rpm up to 600 horsepower at 375 rpm. Smaller protected, self-ventilated motors are also available for continuous operation at 75 centigrade rise. While these motors are nominally rated at 230 volts, d-c, they are selected to obtain maximum power for the drive and to operate at peak voltages of 600 volts and peak currents of 200 per cent. Figure 5 illustrates the rugged, split-steel-frame construction of a medium size motor, with integral bearing heads and broad, sturdy mounting feet. Table III indicates the application of drive motors to several typical sizes of shovels and draglines.

Figure 5. Typical heavy duty, armored, d-c, motion-drive motor with integrally mounted ventilating blower

Motor-Generator Sets

The motor-generator sets for shovel and dragline service are also especially designed for extra-heavy duty, capable of withstanding the shocks and tilt of excavator movement and the high voltages and heavy loads incident to drive motor demand. Figure 6 shows a typical motor-generator set for a large shovel. The set is carried on a heavy, rigid, self-supporting steel base with mounting pads.

D-c generator frames are split for ease of inspection. Solid steel couplings, con-

necting the units on a set, are provided with jacking screws to permit removal of one armature at a time. Each coupling is taper fitted to its shaft to facilitate bearing removal. Typically, each generator is equipped with one large ball bearing, cradle mounted in heavy brackets which are welded securely to the lower half of the generator frame for small and medium excavators, and pedestal mounted for larger equipment. The smaller motor-generator set induction driving motors are equipped with two end-shield type ball bearings. Medium sized synchronous driving motors are equipped with two large end-shield type roller bearings plus a deep groove ball bearing to withstand axial thrust of the set. For the larger equipment, the synchronous driving motors have two pedestal-mounted ball bearings, withstanding both radial and axial loads. Antifriction bearings afford a minimum of maintenance and enable the sets to withstand a higher degree of tilt incident to operation on a grade and motion during propel.

D-c generator armatures are insulated, braced, and banded for the high voltages and currents of this severe duty. Class "A" insulation is entirely adequate for this service. Large commutators must be well seasoned during manufacture to afford long life, low brush wear, and black commutation at high current levels. Generator ratings are selected roughly for the same full load current rating as the motion drive motor, with the kilowatt rating approximately 0.9 of the motor horsepower rating. Generators are available over the range of 21 kw at 1,800 rpm to 375 kw at 1,200 rpm, rated open, 50 centigrade rise, continuous, 250 volts, direct current. Due to the high peak power service they are also constructed for operation at 600 volt and 200 per cent current peaks. Fields are differentially compound wound.

Induction motor-generator set driving motors are provided with special stator winding and end turn bracing due to shock loadings and frequent use of full voltage starting. Class "A" insulation is used. Open, 40 centigrade rise, continuous ratings are available at 2,200 or 3,810 volts from 125 to 500 horsepower at 1,800 rpm. Two hundred and fifty per cent maximum running torque is usually provided.

Figure 6. Typical large shovel or dragline power conversion motor-generator set, showing two hoist, one crowd, and two swing motion generators, constant voltage exciter, and 900 horsepower, 1,800 rpm synchronous driving motor

Synchronous motor-generator set driving motors are designed usually for 225 per cent pull-out torque and special field winding bracing. Class "A" insulation again is used. Open, 0.8 power factor, 40 centigrade rise, continuous ratings are available at 2,200 or 3,810 volts from 450 horsepower at 1,800 rpm to 1,250 horsepower at 1,200 rpm.

Constant voltage exciters for excitation of motion drive motor shunt fields, synchronous motor shunt fields, generator shunt fields, and control are accumulatively compound wound, usually with a flat voltage characteristic from approximately 50 per cent to 125 per cent load. Thermal-magnetic exciter field shunts or other means are provided to compensate for loss in motion power due to ambient and machine temperature rise. Otherwise temperature rise would cause increased exciter, generator, and d-c motor field resistance, and hence, decreased excitation, output, and excavator torque and power. The operating temperature range on an excavator may well vary from −25 to +75 centigrade. Class "A" insulation is used. Open, 50 centigrade rise, continuous ratings are available at 125/125 volts, direct current, from 6 kw to 40 kw at 1,800 rpm.

Control

Control for adjustable voltage, Ward Leonard drives function to adjust the generator output to the will of the operator or to protect the system from excessive voltage and current. Two basic control systems for adjusting generator voltage output are in use today, magnetic and rotating. Table II compares the two in respect to optimum performance.

Magnetic Generator Field Control

Magnetic control consists of the elements required to adjust a generator shunt field, supplied from the constant voltage exciter, by adding or subtracting series resistance in response to the operator's master switch. Figure 7 sketches a typical magnetic generator field control circuit. Current carrying capacity of master switches is low. Therefore, contactors are used as amplifiers to do the actual work. On high inertia swing motions extra relays, not shown, may be used to prevent too-rapid application of torque by adding time delay between the closing of the accelerating contactors.

In addition to the separately excited generator shunt field thus controlled, a series differential field is wound on the generator main poles to provide sufficient compounding to collapse or "stall" the system at excessive loadings, and hence limit current and torque to approximately 200 per cent. With the stall conditions thus obtained and with no-load generator voltage limited to about 600 volts by the saturation characteristics of the generator, then the intermediate volt-ampere characteristic of the generator, and hence speed-torque characteristic of the motion drive motor, is determined by the amount the generator poles are saturated at no-load. No saturation at no-load would produce a straight-line compounding curve to stall as indicated by the dotted curve in Figure 8. Heavy saturation would produce nonlinear compounding as shown by the heavy curve in Figure 8, to afford high peak power for

Figure 7. Functional circuit schematic of a typical electric d-c Ward Leonard drive with magnetic generator field control

the drive, but would require excessive generator iron and separate excitation and would result in sluggish protective response to shock loads.

Therefore, to augment moderate no-load saturation, the generator main poles are wound with a self-excited, accumulative, voltage field to obtain the desired peak power. The amount of self-excitation, adjusted by resistors, also determined the rate at which regenerative braking can be applied, thereby affording some reduction in the normal, excessive generator currents obtained when "plugging," or suddenly applying full reverse effort to brake from a high speed. When heavy self-field is used, as on a swing motion control, a contactor is often added to weaken the field for rapid voltage decay in emergency.

Since generator saturation and self-field action are employed to obtain high-power speed-torque characteristics, adjustable speed control over a wide range is prevented. Good torque control, however, is provided, as shown in Figure 8.

The shunt fields of the d-c motion drive motors are weakened by inserting series resistance with master-switch-operated contactors to change the motion speed in one direction over the other or to reduce motor heating at rest. On a typical shovel, for example, the hoist motor fields are weakened during lowering and rest, the crowd motor fields during rest only, and the swing motor fields not at all, due to possible resultant generator current transients peculiar to operation of that motion. Dragline hoist and drag motions are controlled like a shovel hoist motion in this respect.

An emergency contactor can be opened at will or in response to motor-generator set overspeed, loss of a-c power, or other protective signals to remove excitation from the generator system and set the motion brakes. For simplification the protective interlocking is not shown in Figure 7.

Rotating Generator Field Control

Rotating control replaces the exciter source and magnetic contactor adjusting means for the generator separate field, the generator self-field, and part of series differential excitation with a separate, a-c motor-driven exciter. Various exciters and control systems are available, known by the trade names of Amplidyne, Rototrol, Regulex, and others. A typical generator field exciter, known as the Amplidyne, is shown in Figure 9. Small, compact, and made up of standard, well-known d-c machine parts, thousands of applications have proved practical freedom from maintenance. Very high amplification and rate-of-response properties are inherent. Low energy fields can be handled directly from the operator's master switches, and the physical size of resistance and control circuit elements is determined by design for ruggedness and long mechanical life alone. Space requirements are low. Master switch contact interrupting duty and resistor heating are so minimized as to warrant little maintenance.

The high response rate of this generator field exciter, in conjunction with control circuits which cause momentary overvoltage across the generator field during acceleration and retardation, produce forcing or high dynamic response of the motion to the operator's controller. The characteristic compounding curve of the generator can be shaped and realized more closely to obtain more dynamic or peak power and still remain well inside the commutation limits of the d-c generators and motors. Series or generator current differential action is generally applied to both the generator main poles and generator field exciter to force generator voltage collapse under heavy shock loading. The shape of this compounding curve from no-load to stall can be obtained by the use of generator and exciter saturation, augmented by generator or exciter voltage applied to an accumulative exciter field, or by powerful differential generator current compounding applied to the exciter after normal generator load is exceeded, as determined by an adjustable external reference voltage or "bias." The latter arrangement, as shown in Figure 10, is referred

Figure 8 (left). Speed-torque characteristics available from electric d-c Ward Leonard drives, with magnetic generator field control

Figure 9. An Amplidyne unit, typical of a generator field exciter for rotating control

to as the well-known current-limit scheme and provides very high peak power, good shock load response, and adjustable speed control, indicated by the characteristic curves of Figure 11(a). In this scheme (solid lines of the circuit in Figure 10) the generator separate field is excited by the Amplidyne, whose excitation is derived through its control field from the constant voltage exiter and adjusted directly by the operator's controller. When generator current, as measured by the drop across the generator series fields, exceeds a predetermined value, adjusted by the "bias" resistor, the Amplidyne current field provides heavy differential compounding toward stall.

The former scheme, using machine saturation, provides good peak power, adjustable torque control, and good "plugging" control for protection of electrical and mechanical parts of high inertia systems undergoing rapid acceleration or braking. But since saturation is used, it provides no-load voltage limit only and hence very little adjustment of voltage or speed by controller manipulation. Figure 11(b) shows the basic characteristics obtainable from this arrangement. This circuit may be identified from Figure 10 by simply removing the bias resistor and rectifiers in series with the current field and by connecting in the same current field and the additional generator voltage field through the dotted lines shown. The circuit, except for the addition of the Amplidyne, becomes quite similar, then, to the 3-field system described under magnetic control.

Or by a slightly different circuit connection both generator current and generator voltage can be regulated instead of limited, to afford the completely adjustable characteristics shown in Figure 11(c).

Figure 11. Speed-torque characteristics available from electric d-c Ward Leonard drives, with rotating generator field control

Therefore the control, though simple, is capable of great flexibility of adjustment to meet all the operating requirements of any shovel or dragline motion. Hence the motions on an excavator can be co-ordinated to the best advantage for greatest output and minimum operator fatigue.

Shovel and Dragline Power Sources

A-c power systems supply the majority of power for shovels and draglines in service, and therefore the discussion deals primarily with the requirements and apparatus involved in the distribution of a-c power.

Engines are used as a source of power or prime mover essentially only on smaller excavators. Fuel must be made available at the excavator location. The energy of the fuel must be liberated in an internal combustion engine before mechanical application to the clutch or electric motion drive, and therefore energy reserves and momentary overload capacity are limited. Engines can absorb very little mechanical energy and therefore regenerative braking is not available. Space and weight requirements are usually very high. Therefore, engine sources are used primarily only where a high degree of portability is required, where operations are remote from convenient a-c power systems, or where the temporary nature of the operation does not warrant installation of a-c distribution equipment.

Shovel and Dragline Power Requirements

Energy and power requirements for shovels and for draglines are shown in Figures 12(a) and 12(b), respectively, in relation to dipper and bucket capacity. The values indicated are average for dipper or bucket loading, digging conditions, and excavator builders' design.

Energy requirements are shown in terms of kilowatt-hours per cubic yard of dipper or bucket capacity for average digging conditions and normal movement of the material. Energy consumption will be greater or less as the digging conditions become more severe or easier.

The highest average load for any 15-minute period is called the 15-minute average demand and is measured in kilowatts.

Momentary peak loads during operation are expressed in kilowatts. Total kilovolt-ampere peaks impressed on the power distribution system can then be determined, knowing the power factor of the shovel or dragline load system. Electric shovels and draglines up to a dipper or bucket capacity of eight cubic yards are powered through induction motor drives with average power factors of approximately 80 per cent lagging, and peak power factors approaching 85 per cent lagging. Above eight cubic yard capacity they are powered through synchronous motor drives with average power factors of approximately 90 per

Figure 10. Functional circuit schematic of a typical electric d-c Ward Leonard drive with rotating generator field control

Figure 12. Power requirements for shovels and draglines

Figure 13. Typical package substation for shovel and dragline service, showing switchgear, transformer, and ground protective equipment

cent leading, and peak power factors approaching 97 per cent leading.

A few shovels equipped with counterweighted hoist motion will have 15-minute demand and momentary peaks somewhat lower than shown.

System Voltage Regulation and Power Factor Control

High momentary peak loads must be handled by high-torque motor-generator set driving motors. Since induction motor torque varies with the square of applied voltage and synchronous motor torque directly with applied voltage, it is important that the terminal voltage be maintained as close to rated value as possible. Voltage dips of five per cent will not cause trouble, but dips of 10 per cent may seriously affect continuity of operation.

Where synchronous motors are used, reactive kilovolt-amperes can be added to or subtracted from the power system to stabilize heavy load or light load terminal voltages. This is accomplished by the application of 0.9 power factor synchronous motors whose field excitation can be controlled. Usually a single contactor, actuated by the hoist motion master switch to approximate peak load conditions, serves to cut out resistance in series with the motor field to increase its excitation. Where voltage fluctuations are severe, a stepless synchronous motor field regulator is applied. A typical equipment consists of an Amplidyne, connected buck-boost with the synchronous motor field and constant voltage exciter. The amount of buck-boost is governed by a simple regulator looking at system power factor and load.

System Fault Protection

Particularly on the larger machines with high fixed charges, and with mine output depending on continuity of operation, power system reliability is very important. Outages due to lightning, accidental damage, or line, cable or apparatus fault must be kept to a minimum. High quality distribution apparatus is well worth the investment as insurance alone.

Should machine or system faults occur, the damage and outage must be confined to as small an area as possible. Systems supplying a number of excavators can be arranged easily so that temporary loss of one excavator or its feeder will not shut down any of the others, even momentarily. Therefore, fast, selective tripping of an excavator feeder on line-to-line or line-to-ground fault is provided in modern distribution systems of this nature.

To protect personnel on occurrence of line-to-ground faults, fault current must be limited to a low value so that voltage drops on exposed parts of the ground return path are kept below dangerous levels. A 50 ampere maximum ground current is safe and a convenient level for relaying for fault clearing purposes. The ground-current limit is accomplished by inserting a resistor at the neutral or Y point of the distribution transformer secondary. If the transformer secondary is delta connected, an artificial Y point is established by the use of a zigzag grounding transformer or other means.

Power Distribution Equipment

Since power is usually received at the mine or quarry at transmission voltage levels, a transformer with grounding resistor and protective switchgear must be provided. Power is usually distributed at 4,160 volts, occasionally at 2,400 volts. Cable costs vary almost inversely with the distribution voltage level. In addition, a 4,160-volt grounded system facilitates proper grounding protection.

Substations

A package substation like that shown in Figure 13 provides a co-ordinated, high-quality equipment ready for outdoor installation. This package substation consists of an incoming line structure, a transformer with neutral grounding resistor, and one or more switchgear

Figure 14 (a). Substation transformer capacities for shovels and draglines

Figure 14(b). Diversity factor

units. The incoming line is provided with disconnects, high voltage fuses, and lightning arresters. The transformer capacity required for various shovels and draglines is shown in Figure 14(a). Diversity factors for the use of more than one similar excavator from the same transformer are indicated in Figure 14(b). The grounding resistor is insulated, protected, and connected to the transformer neutral bushing through a current transformer for relaying and tripping.

The switchgear may provide single or multiple feeder circuits. A transformer secondary circuit breaker is desirable in the latter case. A feeder unit consists of a power circuit breaker with three current transformers and over-current relays to afford instantaneous, selective, line-to-line and line-to-ground fault protection. The same inverse-time relaying protects against cable overload. For back-up line-to-ground fault protection, single-circuit feeder or transformer-secondary circuit breakers are time-delay tripped from the current transformer in the ground return circuit. Power circuit breaker interrupting capacity must meet the short circuit duty of the power system at the transformer secondary. Interrupting levels of 50,000 kva are quite common.

Cable

Power can be distributed from the substation by cable or pole line, determined by working conditions. Cable provides a flexible system since it is portable and can easily be shortened or extended in convenient standard lengths. Lengths of 1,000 to 1,500 feet are commonly used and are easily joined by standard couplers. These cable couplers are safe, light-weight, water-tight, are used on switching units as well, and can be mechanically interlocked with distribution circuit breakers. Two, three, and four cable junctions can be provided at a single coupler.

Cable for distribution and feeder circuits is available in 60 and 75 degrees centigrade temperature ratings. For estimating purposes only, Figure 15 indicates the 3-phase cable conductor size in relation to average or normal excavator dipper or bucket capacity. Counterweighted machines require slightly smaller cable ratings. Figure 15 is based on the use of 75 centigrade rated cable. Cables for lower temperature ratings will be proportionately larger. For very long cables, voltage drop must be considered. Good cable conductor insulation consists of a heat-resistant Neoprene-type jacket, braided with a ground sheath. Cable interstices carry three ground conductors and are filled with jute for flexibility and conductor cushion. Cable protection consists of an inner Neoprene-type cushion-base jacket, a reinforcing twine braid, and a tough Neoprene-type outer jacket that is more than twice as resistant to wear and tear than natural rubber.

Cable Switching Stations

Where shovel and dragline power circuit cables branch off from a main distribution feeder cable, portable switching stations, sometimes called cable skids, are used to provide a cable junction and selective fault protection. Figure 16 shows a typical unit. These cable skids can serve any number of functions in the distribution system. A power circuit breaker of suitable interrupting capacity,

Figure 15. Cable ratings for shovels and draglines

Figure 16. Typical portable cable skid for protection and distribution of power from main feeder cable to individual excavator cables

three current transformers with relays for line-to-line and line-to-ground fault protection, and cable couplers for incoming and outgoing power and several load circuits are provided. All cable couplers are suitably interlocked with switchgear, and the system ground wire is physically extended through and connected to all couplers and skids to protect personnel.

Shovel and Dragline Switchgear

On board the shovel or dragline, switchgear is provided for control of a-c driving motors. At present a maximum interrupting capacity of 50,000 kva is considered sufficient. Usually only undervoltage protection is furnished with this gear, since the distribution system provides overcurrent protection for both machine and cable.

Low Voltage Transformer Stations

Since low voltage power must be provided to service drills and pumps, low voltage portable transformer skids can be used to complete the distribution system. Transformation from the 4,160 or 2,400 distribution voltage to the 460- or 230-volt service, load switching, and line-to-line and line-to-ground fault protection are provided. The equipment is mounted on a portable skid and designed for cable connection to the shovel and dragline distribution system.

Although present surface mine power distribution voltages are limited to 4,160, consideration is being given to the 6,900-volt level, since even larger shovels and draglines are being proposed. The convenience and lower cost of smaller cable and distribution equipment must be weighed against the somewhat greater cost of higher voltage main a-c motors on board the excavator.

Discussion

H. S. Jacobs (Harnischfeger Corporation, Milwaukee, Wis.): Schwedes and Stoetzel have given a most excellent discussion of their subject. There are two points upon which I believe additional information is in order. These are:

Under Clutch Drives the statement is made that the prime mover must have higher torque (this is horsepower at a given rpm) than required for other systems. Our experience is that this is not true where eddy clutches are used. For example, we find that a prime mover producing a peak horsepower output of 340 is sufficient for a four cubic yard shovel equipped with an eddy current clutch on the hoist and Ward Leonard on other motions. The prime mover in this case was a Diesel engine. However, a shovel with Ward Leonard electric drive throughout, we find, requires not less than 30 per cent more peak power, which of course means 30 per cent more torque where comparable speeds are considered. Am I, therefore, correct in assuming that the statement above was meant to apply only to shovels with friction clutches and not to shovels equipped with electric clutches?

The second item is:

We have found where induction control is used that an infinite number of controller steps is available. This enables us to cover the entire area between the step lines shown under Figures 3(a) and (c) as well as by the step lines shown. This gives us satisfactory dipper control under any condition of loading. This is true even though the tendency of the equipment is to respond as shown under Figure 3(c). Is the size of the shovel or the number of controller steps the deciding factor in determining the characteristics required under Figure 3(a) with Amplidyne or 3(c) with magnetic control? If the answer indicates that the shovel size is the determining factor, please state which of your types of control you would recommend for shovels of 6 cubic yards or less in capacity.

W. H. Schwedes and D. Stoetzel: The first point under discussion concerns clutch drives. By definition a clutch (or coupling) transmits torque so that the ratio of driven to driving torque remains constant at unity regardless of speed. A torque converter transmits torque so that the ratio of driven to driving torque increases as driven load torque increases at the expense of driven speed. This is equivalent to a stepless changing of gear ratio. When clutch drives are used, and this applies to friction, electric and hydraulic clutches (except torque converters), the maximum speed and torque ratings of the prime mover determine the available motion drive characteristics. Since the gear ratio of the mechanical connection from a clutch to the actual motion is not changeable, when once determined by the excavator builder, only by the use of high torque, high speed, and hence high power prime mover ratings, can both low speed-high torque and high speed-low torque operation be obtained. Reference to Figure 4 illustrates this point.

On the other hand, since a Ward Leonard drive is a true torque converter, the drive may be powered at a moderate power level with high maximum torque machines, and then high torque is converted automatically to high speed when the load is light. This is an electrical equivalent of stepless gear changing, which cannot be accomplished with a clutch drive.

It is true that a clutch drive with normal power rating can afford either high speed or high torque by proper prior selection of speed level and gear ratio, but not both without extra power capacity of prime mover. A compromise between oversize prime mover and high speed at light load usually results. In addition, where the clutch prime mover is a squirrel-cage induction motor wherein maximum torque drops as the square of a line voltage dip, extra high torque must be provided to meet a heavy stalled load demand.

In a Ward Leonard drive, however, a heavy stalled torque is reflected back as high d-c armature current only, and not as a peak power demand on its prime mover.

The second point under discussion concerns the number of controller steps indicated in the families of speed-torque characteristics shown by Figure 3. It was not the intent of the paper to select the exact number of controller steps to be used. A typical controller with five steps was selected for illustrative purposes. What is important to good control is the relative shape of the family of speed-torque characteristics. Note the differences between the curves of Figures 3(a) and 3(c), wherein the basic outside or limiting characteristics are the same, but the slopes on intermediate controller points differ widely. This means that the rate of automatic gear changing, or torque conversion to speed as load changes, can be altered at will by the operator. With a little practice, the operator soon finds that one of the controller points affords just the right gear changing characteristics, so that he can coordinate that motion with another without continual, tiring manipulation of the controller.

For other motions on the shovel or dragline other families of characteristics are required, as described in the paper. Figure 11 shows that with rotating control of a Ward Leonard drive three widely different characteristic families are available. It is even possible to change from one to another by minor circuit variation only. Each has its place.

Ordinarily the clutch drive affords only one family of characteristics, with the basic limiting characteristic similar to that shown in Figure 4, and the intermediate steps relating to it as in Figure 3(c). Smooth, adjustable torque control only is provided, with the shape or slope of the characteristics determined by prior design.

The Reversing Cycle of Modern Blooming Mills

T. B. MONTGOMERY
MEMBER AIEE

J. F. SELLERS
MEMBER AIEE

WHEN the engineer in the metal processing industry today plans to equip his plant with the latest in rolling mill machinery for reducing ingots to slabs, blooms, or bars, he automatically contemplates the specification of a d-c motor drive with a rotating regulator control. He has available considerable operating experience with this equipment to substantiate his judgment. To completely justify the selection it then becomes highly desirable to be able to predict in advance the results to be expected from a drive of a given horsepower, particularly during the reversing cycle.

By proper preliminary calculation of a modern control and drive system it can be shown that a close approximation of currents, voltages, and torques to be expected during the reversing cycle may be obtained. A valuable means for predicting the reversal time and the reversal characteristics of the drive is thus assured; the proper specification of equipment for obtaining maximum results becoming clearly outlined in the process.

A study is made in this paper of a typical blooming mill with a d-c variable speed motor drive rated at 7,000 horsepower, 40/100 rpm, 700 volts. By comparing the variable speed drive with the equivalent necessary ratings in single-speed motors the variable speed selection can be justified.

Accepting the control complications involved by this selection, calculations are made for the ideal desired reversing cycle. These calculations determine the theoretical excitation, control, and power characteristics necessary to attain desired results. By modifying the theoretical data to suit economically practical equipment a forecast of the anticipated reversing cycle can be made. Field tests substantiate the practical accuracy of the theory.

Characteristics of the Drive

For the rapid reversal of a mass of large WK^2 value, such as that of a blooming or slabbing mill, the application of a drive which would apply constant torque over the complete cycle of full-speed forward to full-speed reverse and vice versa, might, at first sight appear desirable. The torque uniformity and smoothness would be ideal from the mechanical point of view. Furthermore, for the electrical drive of such load a single speed d-c motor could be used with variable voltage control, speed reversal being accomplished entirely by generator voltage. With present-day methods, uniform acceleration with current limit control could be accomplished with relatively simple equipment.

A single speed motor of 7,000 horsepower operated at a fixed field to produce 100 rpm at full voltage would withstand 225 per cent load repeated frequently. With a motor armature WK^2 of 2.15×10^6 and a mill WK^2 of 0.08×10^6, making a total of 2.23×10^6 pounds feet,^{2} 83 per cent rated motor current would be required to reverse the empty mill rolls and motor uniformly in 4.55 seconds as shown by the broken line n'' in Figure 6. Thus approximately 143 per cent rated motor torque would remain for doing work on the ingot.

From the electrical point of view such a drive is inefficient inasmuch as it utilizes only the average or one-half of the peak available horsepower over the entire cycle. Field weakening control utilizes a greater percentage of average horsepower. Also from the standpoint of the job to be done, heavy torques are required for the large reductions in the first few passes when the ingot is short and high speed cannot be utilized. Likewise a margin in torque is required for "cold" ingots and special alloys. The motor under study, 7,000 horsepower with speed range 40/100 rpm giving $2^1/_2$ times the torque per ampere at base speed as at 100 rpm, provides this margin.

A single-speed motor with torque equal to the base speed torque of this motor would require a rating of 17,500 horsepower, with proportionately large generators. Using 75 per cent of full-load current the reversing time of such a single-speed motor is shown by line $n'n'$ in Figure 6, which would cut off approximately 1.5 seconds of the reversing time.

With 40/100 rpm speed range in the motor, with corresponding $2^1/_2$-to-1 range in torque, heavy reduction first passes are adequately taken care of at low speeds with short ingots and ample speed is available after the ingots have been elongated to maintain production schedules. Therefore, this choice is the most economical for the job to be done.

The Ideal Reversing Cycle

The major problem in controlling the drive accurately is occasioned by motor field weakening as the following discussion is intended to demonstrate.

Let us consider that the 7,000-horsepower motor in question has ample capacity to handle repeated loads of 175 per cent frequently at high-speed weak-field setting. If we start the study of the reversing cycle at full-speed forward (100 rpm), the first part of the cycle is, of course, that of strengthening the motor field. If 75 per cent horsepower is allotted to the reversal of the mass, then 100 per cent of rated horsepower remains avail-

Paper 48-271, recommended by the AIEE mining and metal industry committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted August 4, 1948; made available for printing September 10, 1948.

T. B. MONTGOMERY and J. F. SELLERS are both with the Allis-Chalmers Manufacturing Company, Milwaukee, Wis.

able for supplying load on the acceleration part of the cycle. As a consequence, the ideal reversing cycle study is based on reversing an empty mill with armature current maintained constant at 75 per cent. Since the generator voltage is held constant at full value during the motor field weakening and motor field strengthening portions of the cycle, the horsepower acting to decelerate and accelerate the motor will remain constant with 75 per cent rated current flowing.

Equation 8 in the Appendix shows that at this current value the motor will be decelerated from 100 to 40 rpm in 1.63 seconds, which time is based on constant current as expressed in equations 6 and 8.

Since this requires constant counter electromotive force the field flux must be changed inversely as speed decreases from 100 to 40 rpm. If flux is not increased in the right proportion counter electromotive force and decelerating current may rise sharply to high peak values. High peak currents are to be avoided since they adversely effect commutation and put undue strain on the equipment.

However, the maintenance of constant counter electromotive force during speed change, so as to keep constant current with constant applied voltage, is dependent on the value of inductance L. But the value of L is not constant. In fact, due to the high degree of saturation at full-field current, the quantitative value of L changes widely from minimum-field current to full-field current. High flux density is employed in the motor at base speed to obtain most economical use of material.

Consequently, a step by step method of calculating motor speed and current is necessary since the motor saturation curve cannot be represented by a single equation. The method of calculation is shown in the Appendix for increments of 5 rpm. In Table I, column (3) dt is computed from equation 6 which gives the average for each increment of 5 rpm $(n_0 - n_1)$. The total field voltage required to give a flux rate of change such as to maintain constant counter voltage is plotted as curve d, Figure 2. This curve is the summation of L_{MF} di/dt (curve b) and ir_{MF} (curve c). For both deceleration and acceleration by motor field weakening total field voltage is shown as curve E_{MF}, Figure 6. It is to be noted that at the first instant of deceleration motor field voltage is changed from its steady-state value of ir_{MF} or 31.4 volts to $ir_{MF} + L_{MF}$ di/dt or 62 volts.

In like manner calculations are made in the Appendix for generator field voltage E_{GF} required to produce a rate of change of flux required to maintain 75 per cent decelerating and accelerating current during the portion of the cycle produced by reversal of generator voltage. This curve is shown as E_{GF} in Figure 6.

The IR drop of the armature circuits has not been used in the calculations as there would be slight effect on the curves, and has not been used because the machines change from motor to generator action during reversal.

The Control

The simplified diagram of control to accomplish the foregoing performance is shown in Figure 3. Generators (1), (2) and (3) connected in parallel have interconnected series fields for holding a balance of load between them.

The motor (4) has its excitation supplied by motor exciter (5) which in turn has its excitation supplied by Regulex exciter (6). The generators have their excitation supplied by generator exciter (17) which in turn has its excitation supplied by Regulex exciter (12).

The reference or speed setting fields (13) of the generator Regulex exciter and (8) of motor Regulex exciter are energized from a constant potential source through the mill master. Balance field (9) in

Figure 3. A simplified typical schematic diagram of a reversing blooming mill control

the motor Regulex exciter opposes the reference field (8), being energized from the voltage across resistor "R1," a measure of motor field current. Balance field (14) in the generator Regulex exciter opposing the reference field (13), is energized from the voltage of the generators (1), (2) and (3). Two other fields are supplied on each Regulex exciter, voltage limit fields (10), (16), and current limit fields (11), (15).

The mill master is arranged so that the first steps energize the generator Regulex reference field in the forward or reverse direction, the motor Regulex reference being held meanwhile at its maximum value. The generator voltage rises to balance the Regulex reference, and the next steps of the mill master reduce the motor Regulex reference. This causes the motor field to weaken until the Regulex exciter balances and the motor runs at topspeed, having attained the acceleration first by the rise of generator voltage then by a weakening of the motor field. Deceleration reverses this process.

Control means not shown energize contacts "G" and "M" at the proper point in the cycle so that the correct current limit field is in control. The same means is employed to properly sequence the Regulex reference fields in case of a rapid reversal of the mill master.

Figure 4. The no-load saturation curve of a generator rated 2,000-kw 700-volt 514/436-rpm at 93 per cent synchronous speed

Predicting the Practical Reversing Cycle

Consideration of Figure 6 makes it evident that the required peak voltage of motor and generator exciters is beyond practical limits for both economical size and rate of response, so a compromise is made by setting a 250-volt nominal rating on the exciters. The flux density is kept low in the exciters to provide fast exciter response and good control. In order that the absence of these peak exciter voltages at and near the point of saturation of the motor and generator fields may not be detrimental to the reversing cycle, by allowing the armature current to be reduced sharply at the points where they are shown in Figure 6, the generator field control is set to overlap motor field control in time. By this means the limits in exciter voltage have no effect on over-all reversing time.

A more important factor encountered in the attempt to set performance to the ideal is the item of time constants. In Figure 6, the curves of required field voltages E_{MF} and E_{GF} change from their steady state value to their transient values instantly. This obviously is not possible in practice.

Since a motor speed change is initiated by a change in the speed setting field of the motor or generator Regulex pilot

Figure 5. Curves showing a speed change on the motor of Figure 1 from +40 to −40 rpm by variable voltage control, depicting the required generator field voltage components. Accelerating torque is 75 per cent rated horsepower. Three generators similar to Figure 4 are used

a—rpm (n) c—$L_{GF}\, di/dt$
b—ir_{GF} d—field volts (3 generators)

Figure 6. Combination of Figure 2 and Figure 5 to show full operation from +100 to −100 rpm using 75 per cent armature amperes and no overlapping of motor and generator field changes

exciter, Figure 3, the change in motor or generator field will be along an exponential curve composed of four factors.

1. Regulex exciter field time constant (16, 12, Figure 3)

2. Main exciter field time constant (5, 17, Figure 3)

3. Motor or generator field time constant (1, 2, 3, 4, Figure 3)

4. Damping effects of solid magnetic parts, chiefly in the motor or generator frame.

A reversing time of 4.55 seconds as shown to be possible theoretically in Figure 6 has been attained in practice but the accelerating current was not held constant. Furthermore, it has been found in several cases that full advantage could not be taken of this short reversing time because of time required by approach tables, manipulators, screwdowns, and so forth. Further study of these auxiliary devices will, no doubt, be done in the future.

Taking into account these several factors, calculated performance curves of the reversing cycle are shown in Figure 7. These curves include the overlapping of generator field control and motor field control as well as the reducing of the initial decelerating current to 50 per cent, instead of the 75 per cent as in Figure 6, so as to lengthen out the reversing time to approximately seven seconds.

The Reversing Cycle in Practice

The motor shown in Figure 9, drives a reversing mill under the direction of a control similar to Figure 3. The curves of Figure 8 show the various values corresponding to those calculated in Figures 6 and 7, as plotted from an oscillogram of the reversing cycle taken during operation of the mill. It is to be noted that the numerical values of the curves in Figure 8 in general follow those predicted by calculated values represented by the curves of Figure 7. In fact, the values of Figure 8 are somewhat more favorable than those of Figure 7.

The points in the cycle departing from the desired theoretical are:

1. Due to factors 1, 2, 3, and 4, given previously, about one-half second is required for the current to rise, to the desired value at the beginning of deceleration. This lengthens the actual reversing time.

2. There is insufficient motor field voltage during the latter part of the motor field strengthening portion of the cycle, prior to the start of generator voltage reversal. This causes the current to be reduced and with it the rate of deceleration is lessened at this point.

3. Near the end of generator voltage reversal and at the beginning of motor field strengthening there is insufficient forcing voltage on both motor field (E_{MF}) and generator field (E_{GF}) to maintain desired accelerating current. However, as Figure 8 shows, the motor reverses the empty mill in approximately seven seconds with an average armature current of approximately 50 per cent.

Conclusions

1. It is possible to predict by calculation close approximations of current and voltage values during the reversing cycle.

2. By proper selection of exciter voltages and the use of rotating amplifier type control, a shorter reversing time is possible than previously was accepted as satisfactory.

3. By close attention to the factors in machine design affecting time constants, including laminated frames of main motors, generators, and exciters, a still shorter reversing time is possible and problems effecting commutation are made easier.

4. A shorter reversing time requires faster operation of auxiliaries such as approach tables, manipulators, and screwdowns, if an over-all gain is to be realized.

5. It becomes an evident fact from the data that a practical reversing mill control must have exciters with a voltage range 250–300 per cent greater than the required *IR* field voltage. Laminated construction would reduce this forcing voltage requirement approximately 25 per cent.

Appendix

These calculations are for a 7,000-horsepower d-c reversing motor with the following characteristics:

Volts—700.
Amperes—8,000.
Speed—40/100 rpm by shunt field control.
Poles—24.
Armature $WK^2 = 3.22 \times 10^8$ pounds per square feet.
Reversing time = 40/40 rpm in 2 seconds, 100/100 rpm in 7 seconds (accepted commercial practice).
Shunt field = 22 turns per pole.
Shunt field = 0.19 ohms resistance at 25 degrees centigrade.
Shunt field = 444 amperes at 40 rpm, full load; 508 amperes at no load.
Shunt field = 130 amperes at 100 rpm.
Flux per pole = 50.8×10^8 at 40 rpm, no load.
Armature and *IP* resistance = 0.00340 ohms at 25 degrees centigrade.

To change the motor speed from 100 rpm to 40 rpm by field strengthening, the motor field voltage is calculated as that required to maintain approximately 75 per cent of full load armature current during this speed change.

The generator volts remain at 700 throughout. The time in seconds t to change speed from n_o to n_i rpm is

$$t = \frac{WK^2}{(T)} \times (n_o - n_i) \times 0.003252 \qquad (1)$$

which is obtained directly from the fundamental equation:

Force = mass × acceleration

$$T = K_1 \times \phi \times I \qquad (2)$$

Also

$$T = \frac{hp \times 5{,}250}{(n)} \qquad (3)$$

or the full load torque of this motor at 40

Figure 7. The calculated full reversal cycle with the motor and generator field controls partially overlapping for seven seconds total reversing time

Figure 8. Curves made from an oscillogram of a typical reversal of the motor of Figure 1

Figure 9 (left). A 7,000 - horsepower, 40/100-rpm 700-volt d-c motor, driving a hot reversing mill

Figure 10. A typical hot reversing mill in action

$$\text{rpm base speed} = \frac{7{,}000\times5{,}250}{40} = 0.92\times10^6$$

foot pounds.

Combining equations 2 and 3,

$$T = 0.92\times10^6 = K_1\times50.8\times10^6\times8{,}000 \qquad (4)$$

or

$K_1 = 2.26\times10^{-6}$ for this motor.

Combining equations 2 and 4

$$T = 2.26\times10^{-6}\times\phi\times I \qquad (5)$$

Combining equations 1 and 5

$$= \frac{WK^2\times(n_o - n_t)\times1{,}440}{\phi\times I} \qquad (6)$$

$$\text{Motor counter emf} = K_2\times\phi_n\times n \qquad (7)$$

or at a base speed, no load,

$$K_2 = \frac{700}{50.8\times10^6\times40} = 0.334\times10^{-6}$$

Then

$$\phi_n = \frac{700}{0.344\times10^{-6}\times n} = \frac{2{,}030\times10^{-6}}{n}$$

Combining equations 6 and 7

$$t = \frac{WK^2\times(n_o - n_t)\times1{,}440\times n}{2{,}030\times10^6\times I} \qquad (8)$$

But n is the average speed between n_o and $n_t = \frac{n_o + n_t}{2}$ so

$$t = \frac{WK^2\times(n_o^2 - n_t^2)\times0.352\times10^{-6}}{I}$$

seconds for the range of motor speed accomplished by motor field change.

Thus using 75 per cent of the 7,000 horsepower full load rating for decelerating from 100 rpm to 40 rpm, and a total motor and mill WK^2 of 3.3×10^6, the time required

$$t = \frac{3.3\times10^6\times(100^2 - 40^2)\times352\times10^{-6}}{0.75\times8{,}000}$$

$$= 1.63 \text{ second}$$

The instantaneous volts required on the motor shunt field to maintain a constant counter electromotive force to produce 75 per cent armature current while motor speed is changing will be

$$e_{MF} = ir_{MF} + L_{MF}\frac{di}{dt} \qquad (9)$$

But

L_{MF} = number of poles × turns per pole × $d\phi$ henries ÷ $di_{MF}\times10^8$ (10)

$= \frac{d\phi}{di}\times5.28\times10^{-6}$, where ϕ = flux lines per pole at i. So

$$e_{MF} = ir_{MF} + \left(\frac{d\phi}{di}\times5.28\times10^6\times\frac{di}{dt}\right) \qquad (11)$$

$$= ir_{MF} + \left(\frac{d\phi}{dt}\times5.28\times10^{-6}\right)$$

Table I and Figure 2 show the required shunt field voltage components ir_{MF} and $L_{MF}di/dt$.

These two components of motor field voltage during field strengthening are obtained as follows:

A. Plot motor speed versus motor field ampere curve, Figure 1.

B. Calculate motor flux versus time (column 2, Table I from equation 7).

C. Calculate speed versus time curve a, Figure 2, (columns 3 and 4, Table I), by using equation 6.

D. Calculate $d\phi$ for each increment of speed (column 5, Table I).

E. Calculate $d\phi/di \times 5.28 \times 10^{-4}$ and plot as curve b Figure 2 (column 6, Table I).

F. Record shunt field amperes from Figure 1 for each speed point (column 7, Table I).

G. Multiply field amperes by r_{MF} hot to get e_{MF}, column 8, Table I, and plot as curve c, Figure 2.

H. Add curves b and c Figure 2, to obtain total field volts curve d.

The motor speed change between +40 rpm and −40 rpm occurs with constant motor field of 58 amperes, generator voltage changing from +700 volts to −700 volts at a constant rate which maintains 75 per cent of full load armature current in the loop.

Acceleration time t then proceeds by equation 6.

$$\frac{3.3\times10^6\times(n_o-n_t)\times1{,}440}{0.75\times8{,}000\times50.75\times10^6}$$
$$=0.0156(n_o-n_t)=0.624 \text{ seconds}$$

from 40 rpm to 0 rpm.

The two components of generator field voltage to produce the required voltage change are obtained as follows in Table II.

A. Curve a of Figure 5 shows the relation between time t and speed n for the motor speed change by equation 6 with constant torque value equal to 75 per cent of base speed rating (columns 2 and 3).

B. The 7,000-hp motor is driven by three 2,000 kw generators as shown in Figure 3 whose shunt fields are in series and each have the following characteristics:

Poles—14; flux per pole at 700 volts no load, 93 per cent of synchronous speed = 7.68×10^6; armature and interpole resistance = 0.00975 ohms at 25 degrees centigrade; shunt field = 48 turns per pole; shunt field = 0.109 ohms at 25 degrees centigrade; no-load saturation as per Figure 4, at 93 per cent of synchronous speed; calculate shunt field i_{GF} (column 6, Table II) shown as curve b Figure 5, by the use of saturation curve Figure 4.

C. Calculate flux per pole (column 7, Table II) from the relation: Flux per pole = 0.01096 × volts × 10^6 × 93 per cent of synchronous speed. (see equation 7).

D. Calculate $L_{GF}di$ from the relation

$$L_{GF}=\frac{3\times14\times43\times d\phi}{di\times10^8}$$

or

$$L_{GF}=18.05\times10^{-6}\times\frac{d\phi}{di}$$

or

$$L_{GF}=\frac{di}{d\phi}=18.05\times10^{-6}\times\frac{d\phi}{di}$$

Columns 8 and 9, Table II, shown as curve c Figure 5.

E. Add curves b and c Figure 5 to obtain curve d showing total generator shunt field volts. Figure 6 combines Figures 2 and 5 to show the total speed change of +100 rpm to −100 rpm.

Assuming a ceiling voltage of approximately 250 for both motor and generator field, and a time constant of 1.0 for both exciter systems, a similar calculation to Tables I and II will be made on this more practical basis. The build up of exciter curves are first plotted, then the motor and generator flux obtained by use of equation 11 on a trial-and-error method. Due to the limitation of practical exciter ceiling and response, it is soon found that an overlap of motor and generator field control is required to maintain the armature current, so Figure 7 shows the calculated result using generator field control beginning at approximately 52 rpm on the decelerating cycle. The armature current is figured step by step based on the slope of the speed curve calculated previously from the motor and generator flux curves.

Symbols

Arm = motor armature

L_{GF} = generator shunt field inductance at field current i_{GF}
i_{GF} = generator shunt field current in amperes
r_{GF} = generator shunt field resistance
e_{GF} = instantaneous generator shunt field volts

Discussion

F. M. Scott (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): I would like to emphasize the statement made by Sellers that full advantage could not be taken of the short possible theoretical reversing time because of the time required by approach tables, manipulators, screw downs, and so forth. In fact, the present standard reversing times cannot fully be utilized because of these considerations. While it is true that the operators can quickly determine the difference when the reversing time is changed, the main advantage of faster reversing cycle is the general feeling of the operator. As Harris mentioned earlier, a peppy mill satisfies the operator but does not necessarily increase the tonnage of the mill. We have found that generally the tonnage remains unchanged by either adding or subtracting a second from the reversing cycle, as the steel is actually in the mill only a short portion of the time over an extended period. So therefore, a further study of the auxiliary devices and scheduling is indicated.

Frequency Modulation Receiver Design Trends

G. G. YOUNG
NONMEMBER AIEE

FREQUENCY modulation had its commercial beginning in October 1940[1] when permits were granted to 15 applicants by the Federal Communications Commission (FCC). These 15 stations were located in areas of dense population resulting in service to 20,000,000 potential listeners located within the 50 microvolt per meter contours (the marginal value required by the FCC). A large number of additional applications were on file with the FCC at that time.

The number of frequency modulation (f-m) receivers in the hands of the public in 1940 numbered only a few thousand. Before the entry of this country into the war, however, approximately 400,000 f-m sets[2] had been produced and sold. Most of these were in the deluxe class. In 1940, f-m transmitters were available at a cost comparable to that of an amplitude modulation (a-m) transmitter of equal rating.

By virtue of its noise reducing properties the coverage of an f-m transmitter is better than that of an a-m transmitter of the same power rating. It is apparent, therefore, that the progress of the f-m broadcasting has depended upon the ability of receiver engineers to provide good quality f-m receivers at a price that the public is willing to pay and also upon the ability of the station operators to furnish programs that are competitive with contemporary a-m programs.

The superior features of f-m broadcasting are well known: freedom from noise; genuine high-fidelity reproduction; and freedom from interference and fading. It has been demonstrated that in these respects f-m is superior to a-m and that these advantages are obtainable in practice. It must be borne in mind, however, that these advantages are obtainable only with a well-designed receiver and that the design requirements for f-m receivers are basically more rigid than for an a-m receiver.

In the long run the service rendered to the public by f-m broadcasting will determine the success of the f-m industry as a whole. Initially, however, f-m receiver sales were stimulated by advertising claims that f-m would open a new and better era in broadcasting. Buyers of f-m sets were motivated by the desire to enjoy the superior performance of f-m and a fear that receivers without the f-m range would shortly become obsolete and would therefore be a poor investment.

It is not the purpose of this paper to prove that f-m is or is not to have a permanent place in domestic broadcasting service. The problems encountered in the design of f-m receivers are more difficult, however, than is the case with straight a-m receivers. F-m receiver production costs remain high even though significant advances have been made in the development of low cost components and design techniques have improved steadily. Some of the design problems and the techniques that have been developed will be discussed. In addition, the factors that have resulted in changing design requirements will be considered and the effect of these factors on the cost and complexity of f-m receivers will be discussed.

Prewar Receivers

An ideal f-m receiver would have the following performance characteristics:

1. The audio system would be capable of good reproduction up to 15 kc.
2. A circuit for amplitude rejection would be included ahead of the detector or the detector would be insensitive to amplitude modulation.
3. The receiver would be sufficiently sensitive to reach the threshold of amplitude limiting when operated in a region where the field intensity is no more than the marginal 50 microvolts per meter.
4. The side responses should be small in amplitude so that the tuning characteristic is agreeable.
5. The transfer networks would be linear in both phase and amplitude in order to avoid phase modulation on impulse noise.

A study of these requirements will reveal that the design of f-m receivers is considerably more exacting than that of a-m receivers.

The only practical f-m receiver circuit in 1940 was the Armstrong system consisting of a superheterodyne receiver incorporating a grid-bias limiter and a phase-shift discriminator. Technically it was possible in 1940 to design an f-m receiver having the performance characteristics outlined before. The design of such a receiver within the reach of the general public was a difficult task, however, and the deluxe console was the most common form of f-m receiver.

The design problems encountered by receiver engineers in the 42-to-50 megacycle (mc) range were not basically different from those encountered in the design of a-m short-wave receivers. Oscillator drift became more troublesome because of the small values of circuit capacity required to tune these frequencies but compensation was not difficult. The problem of microphonics was more pronounced because of the higher operating frequencies and the low circuit capacities and because the f-m detector is frequency sensitive. Stability of the radio frequency (r-f) amplifier stage became a more serious problem than it had been at the lower frequencies, largely because of the impedance of the gang capacitor rotor shaft which introduced coupling be-

Paper 48-272, recommended by the AIEE communications committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted August 9, 1948; made available for printing September 14, 1948.

G. G. Young is with the General Electric Company, Syracuse, N. Y.

tween the tuned circuits associated with the plate and grid circuits of the r-f amplifier.

The tubes and components designed for broadcast and short-wave band service perform acceptably at 50 mc. The discriminator circuit, although considerably more complicated and critical than an a-m detector was not new to receiver engineers since use had been made of it in automatic frequency control circuits used in a-m receivers.

Since many of the prewar receivers were designed to reach the threshold of limiting with signal inputs of 10 microvolts or less, the voltage gain required at the intermediate frequency (i-f) was rather high (100,000 times or more). This is more gain than engineers had been accustomed to handling at a single frequency. The intermediate frequency of 4.3 mc chosen to place the image frequency outside the 42-to-50 mc band makes the stability problem much more difficult than at 455 kc. The solution of this problem did not, however, require any particularly new techniques. With experience, engineers were able to obtain stable voltage gains of 75 or more per stage.

Across the 42-to-50 mc band, antenna stage gains of three to four times and r-f stage gains of 18 to 20 times are obtained easily. The use of gang capacitors for tuning, limited the r-f gain of most receivers to something less than 15 times except in the more expensive receivers which used tuning condensers having insulated rotor shafts to isolate the sections from each other in order to prevent coupling between grid and plate tuned circuits. It was this stability problem in the r-f amplifier that led to the development of the General Electric model *JFM-90*, a double conversion superheterodyne.

The *JFM-90* converted in the first stage to a first intermediate frequency which varied from 23.15 to 27.15 megacycles as the receiver was tuned over the 42 to 50 megacycles range. The second convertor mixed the first intermediate frequency with the local oscillator voltage to produce the second intermediate frequency of 4.3 megacycles which was a fixed frequency. A voltage gain of approximately 20 times was obtained in the first convertor. No instability problem was encountered because the plate and grid circuits of the first convertor were tuned to different frequencies. Because of the high order of stable voltage gain obtainable with the double-conversion circuit the *JFM-90* receiver had a quieting sensitivity of approximately 5 microvolts.

Most of the early prewar receivers employed two stages of amplification at intermediate frequency as well as two grid-bias limiters in cascade. Such a circuit, although rather elaborate, was made necessary by the desirability of obtaining acceptable performance even outside of the 50 microvolt per meter service area. The trend in 1941 was definitely toward the dropping of the second i-f stage and it seems certain that the cascade limiter would shortly have been abandoned. The need for more economical designs, the increasing number of f-m broadcasting stations, and the availability of better tubes, such as the *6SH7*, as limiters would certainly justify this trend in design.

To be commercially acceptable the prewar receivers had to include the a-m broadcast band. This fact resulted in receiver designs that were rather complex compared to straight a-m receivers since, unlike the a-m short-wave bands, the f-m portion of the receiver required tuning elements and an i-f channel that were not used for a-m reception. This in addition to the increased design problems due to the higher operating frequencies, the need for an amplitude limiter, and the inherent complexity of a frequency sensitive detector made the prewar f-m receiver necessarily more expensive than the contemporary a-m receivers.

At the late prewar stage of the art, a combination a-m–f-m receiver of good design used only one tube, the limiter, that was not also required in an a-m receiver of good design. If the war had not intervened, and if f-m had been allowed to remain in the 42-to-50 mc range, it is possible that straight f-m receivers might have become inexpensive enough to become popular. This would have depended upon the development of the f-m broadcasting service.

Postwar Receivers

During the war years the FCC became convinced that long distance interference resulting from skywave reflections would become a serious problem as the number of stations increased. Theory and the results of field tests indicated that this type of interference would be negligible in the 100-mc region. During November 1945 the FCC[3] made tests near Washington, D. C., comparing the coverage of a transmitter operating at 99.8 mc to one operating at 43.2 mc. The results indicated that transmission at 99.8 mc was at least as good as at the lower frequency. During January 1947 the FCC[4] assigned frequencies between 88-and-108 mc to all f-m broadcasting stations.

Regardless of the possibility of annoying interference that might have troubled f-m listeners had f-m remained on the 42-50 mc band it must be admitted that the change to the 88-to-108 mc band struck a severe blow to the progress of commercial f-m. What the long run effect of this change will be still remains to be observed. At any rate the change came at a time when f-m seemed ready to make rapid progress. The number of f-m stations in operation at the end of the war was approximately 50 commercial stations plus about 10 experimental stations.[5] All of these were operating in the 42-to-50 mc band and approximately 400,000 f-m receivers were in the hands of the public. Prewar experience, although not resulting in low priced f-m receivers had enabled engineers to solve most of the basic design problems related to the use of the Armstrong circuit receiver. Receivers optimized for operation on the 42-to-50 mc band could have been built to give very good performance on both the a-m and the f-m bands and at a cost very much lower than that of the early postwar receivers, that included not only the 88-to-108 mc band but also the 42-to-50 mc band. It was obvious at the end of the war that a considerable period would elapse before all of the f-m stations were converted for operation at the higher frequencies. Manufacturers felt therefore, that the old f-m band should be included so as to permit immediate service to the purchaser.

Even if the change to the 100 mc band could have been accomplished immediately after the war without the costly and troublesome transition period that was experienced, the problems of receiver engineers would still have been multiplied as a result of this change. Most receiver engineers had little experience with frequencies in the 100-mc range. The experience they did have had been obtained in the design of wartime apparatus where cost was of secondary concern and elaborate precautions could be observed. As a result, engineers had not developed the design techniques that are necessary to obtain good performance at low cost.

Intermediate Frequency Considerations

The desirability of placing the image frequency outside of the 88-to-108 mc band made necessary the choice of an intermediate frequency greater than 10 mc. The 10.7 mc range has become standard with most manufacturers. Whereas only one stage of amplification at 4.3 mc is necessary to obtain the necessary gain and

Figure 1(A). 5-band tuner using Guillotines for frequency modulation and short-wave tuning

Figure 1(B). Bottom view of tuner shown in Figure 1(A)

selectivity, two stages are necessary at 10.7 mc in receivers that use the grid-bias limiter. The lower gains obtained in the r-f and convertor circuits at 100 mc plus the reduced gain and selectivity obtained in an amplifying stage at 10.7 mc as compared to 4.3 mc make two stages necessary. Stability is, of course, more difficult to maintain at 10.7 mc and the added stage results in increased cost.

Tubes

The most obvious problem confronting engineers at the close of the war was the choice of tubes for the r-f and convertor circuits. The conventional receiver tubes, although good enough for use in the 42-to-50 mc range, were very poor at 100 mc. High input conductance and low effective mutual conductance at 100 mc made most of the conventional tubes poor amplifiers and oscillators. The *6SA7*, at that time the best all purpose pentagrid convertor, is a very poor oscillator at 100 mc. Although the *6SA7* will work with the oscillator at half frequency, the conversion efficiency is too low to be useful.

Good tubes, namely the *6AK5* and the *6AG5*, were available at the end of the war but at a cost several times as high as the conventional tubes. An added disadvantage is the poor performance of these tubes on the a-m broadcast band because their sharp-cutoff grid characteristic results in a very poor automatic volume control characteristic and makes them susceptible to overload, with resultant distortion and cross-modulation effects. Even so, the necessity for obtaining high sensitivity on the new f-m band resulted in the wide use of the more expensive tubes as r-f amplifiers, mixers, and oscillators in the early postwar receivers. The demand for low cost tubes capable of good performance on both the low and high frequencies resulted in the development of the miniature types such as the *6BA6*, *6AU6*, *6BE6*, and others. The *6BE6* is an excellent oscillator at 100 mc and has reasonably good conversion efficiency. The type *6S8-GT* and the new miniature type *6T8* have fulfilled the need for a tube combining the functions of discriminator, a-m detector, and first audio amplifier in one envelope.

Tuning Methods

As a tuning device the ganged capacitor had begun to show some deficiencies in the 42-to-50 mc band. At 100 mc, microphonics, amplifier instability due to grid-plate coupling through the rotor shaft impedance, and high contact resistance at the rotor ground points seemed insurmountable problems to many engineers. As a result, many new types of tuners were developed and used. Perhaps the best of these was the permeability tuned coil[6] used by several manufacturers and the Guillotine tuner[7] developed and used by the General Electric Company. Both of these types of tuners have advantages that make them well suited to operation on the new f-m band. The tuned circuits are small units that may be placed in the optimum position on the chassis so that connecting leads are short. Being inductance tuners they present the best obtainable L/C ratio over the complete tuning range. Since each tuned circuit is an individual unit no common coupling need exist. Both types of tuners are reasonably free of microphonic effects and may be designed to provide consistently good circuit tracking in production. The Guillotine tuner consists of a 2-turn coil made of two flat stamped metal parts mounted in accurately molded plastic frames. The inductance is varied by sliding a metal vane between the two turns. Tracking is controlled by the shape of the vane.

Figure 1(A) shows tuner unit used in the General Electric model *417* receiver. The dial mechanism is in the background. The oscillator Guillotine is in the foreground. The r-f and antenna Guillotines may be seen just back of the oscillator section. At the right of the illustration, the permeability tuned coils for broadcast band tuning may be seen. The Guillotine vanes and the iron cores are supported by the elevator platform which can be seen just above the Guillotines. This platform moves up or down to vary the inductance of the tuning elements.

The disadvantage of both the Guillotine and the permeability-type tuners is that they require rather elaborate mechanical linkages which in conjunction with a gang capacitor or tuned coils for the a-m band results in a very expensive tuner assembly. Thus the need for a single unit tuner which functions for both a-m and f-m is indicated. The return to the use of the ganged capacitor is

Figure 2. Circuit used for simplified wafer switching

Figure 4. Reflexed radio-frequency amplifier circuit

now a definite trend. Improved design techniques and reduced emphasis on sensitivity plus economic considerations have resulted in more widespread use of the ganged capacitor for f-m tuning. The increased popularity of wide band (fixed tuned) input circuits has hastened the return to the use of capacitor tuning by eliminating the need for a section to tune the input circuit and thereby eliminating the instability problem that resulted from the impedance of the rotor shaft.

Front End Circuitry

The necessity of incorporating both the new and the old f-m bands as well as the a-m broadcast band in the early postwar receivers resulted in very complicated r-f and convertor circuits with involved wafer switching. Many receivers also included one or more short-wave a-m bands which further complicated the design. The need for short connecting leads and simple switching is hard to fulfill when this number of bands must be designed. The use of a pentode mixer with separate local oscillator in many of the early receivers also increased the complexity of the switching. Figure 1(B) shows the wafer switching assembly which is a part of the tuner shown in Figure 1(A). This switch selects either of the f-m bands, a push button or manual broadcast position or one of two short-wave spread bands which were tuned by the Guillotine coils.

Figure 3. Guillotine tuner used with circuit of Figure 2

The small values of inductance and capacity used to tune the 88-to-108 mc band make wafer switching, particularly in oscillator circuits, very undesirable. A few inches of connecting leads plus the inductance and capacity of the wafer switch contacts may form an appreciable part of the tuned circuit at these frequencies. Temperature and humidity changes cause variations in the capacity of the wafer switch sufficient to cause serious oscillator drift. In many of the postwar sets the wafer switch was the worst cause of frequency drift and certainly the most difficult to compensate because of the wide variations between individual switches of the same type. Another disadvantage of switching in the high-frequency circuits is the difficulty of controlling the length of connecting leads. Variations in the length of these leads cause mistracking of the tuned circuits since the leads are part of the tuned circuits. To compensate for this, the permeability tuners and the Guillotine tuners were designed for a 1-mc overlap at each end of the band. An adjustment of the movable element was provided so that the total range could be adjusted in the direction to compensate for the inductance variation in the connecting leads.

The passing of the 42-to-50 mc f-m band and the elimination of the short-wave a-m bands from most receivers permits considerable simplification of the bandswitching. The use of the *6BE6* type of pentagrid convertor also simplifies the switching and results in a considerable cost saving compared to the earlier convertor circuits which employed two pentodes, each costing more than the *6BE6*, as well as a greater number of components. Figure 2 shows a circuit arrangement which not only reduces switching to minimum, but results in considerably improved performance on the f-m band.

In the circuit of Figure 2, L_1, L_4, and L_5 are Guillotines for tuning the f-m antenna, r-f amplifier, and oscillator circuits respectively. These coils are placed close to the associated tube socket to make the connecting leads short. L_4, the r-f coil, and L_5, the oscillator coil, are wired directly to the proper socket terminals through the coupling capacitors C_8, C_9, C_{12}, and C_{15}. The a-m tuned circuits are connected to the tube sockets through the choke coils L_4, L_6, L_7, and L_{10}, which are made large enough to prevent shunting of the f-m circuits by the a-m coils. S_1 which selects the f-m or a-m antenna circuit and S_2 which disables the a-m oscillator coil when the bandswitch is in the f-m position are the only switches required to change the r-f and convertor circuits from a-m to f-m operation. The a-m oscillator takes control when the receiver is switched to the a-m position. The coupling capacitors for the f-m circuits are small values which act as part of the parallel circuit capacity for the a-m circuits when the receiver is operating on the broadcast a-m band. The chokes used to isolate the f-m circuits act as connecting leads for the a-m coils since their inductance is small compared to that of the a-m coils.

Besides the simplification of the wafer switching, this circuit has the following advantages. The f-m coils constitute nearly all of the circuit inductance because the leads are short and no switching is done except in the grid circuit of the r-f amplifier tube. Temperature and

humidity cause very little change in the capacity across the tuned circuits so that oscillator drift is small and may be easily compensated. The short direct leads in the f-m tuned circuits are easily controlled in production so that consistently good tracking is obtained. Several variations of this circuit have been used in receivers now on the market. One variation, for example, has the high-frequency coils in series with the a-m coils. The f-m coils are wired directly to the tube socket and are not disturbed by switching. The changeover from a-m to f-m is accomplished by disabling the a-m oscillator as in the parallel arrangement of Figure 2.

Figure 3 shows tuner unit used in a General Electric receiver currently in production which uses the circuit of Figure 2. This tuner uses a miniature version of the Guillotine tuner for f-m tuning and a ganged capacitor for tuning the a-m broadcast band. The wafer switch used with this tuner consists of a single wafer which accomplishes the switching functions shown in Figure 2 plus the audio switching required to select the a-m or the f-m detector.

Since two stages of amplification at 10.7 mc are required in receivers using the grid-bias limiter while only one stage is needed for the 455 kc a-m–i-f it is possible to reflex the extra f-m–i-f stage to make it operate as an r-f amplifier on the f-m band. Figure 4 is a simplified circuit showing how this principle is applied in receivers being built by the General Electric Company. This circuit is similar to Figure 2, in that the f-m circuits are connected to the tube sockets through small coupling capacitors and the a-m circuits are connected through chokes to prevent shunting of the f-m circuits. L_1 is tuned to the center of the f-m band by the coupling capacitor C_1 plus the stray capacities and the tube input capacity. C_1 is chosen to make the bandwidth of the input circuit such that the gain at the band ends is about half of the mid-band gain. Broad tuned input circuits have been used in a number of receivers now being marketed. It is possible to obtain performance with this circuit that is essentially as good as with a continuously tuned circuit. The r-f voltage developed across L_1 reaches the grid of the r-f tube through the secondary of the first f-m–i-f transformer. After amplification, the r-f is applied to the convertor stage. The circuits just described make use of the standard low-cost miniature tubes such as the *6BA6* for r-f and i-f amplification and the *6BE6* pentagrid convertor. The use of these tubes plus the simplicity of the circuits results in considerable cost saving compared to the early postwar r-f and convertor circuits.

Detectors and Amplitude Limiters

Most of the f-m receivers built during 1946 used the grid-bias limiter and the phase-shift discriminator. No basic improvements have been made in the grid-bias limiter but its operation was improved over prewar limiters by the use of high mutual conductance tubes such as the *6SH7* and the *6AU6*. It was the practice in prewar receivers to make the discriminator bandwidth approximately 200 kc. The trend since the war has been toward discriminator bandwidths of 400 kc or wider. This results in much lower side responses and a broader main response, so that the tuning characteristic is much improved. The wide main response tolerates a considerable amount of drift before retuning of the receiver is required.

Even with the high mutual conductance tubes now used as limiters, the level required for saturation of the grid-bias limiter makes necessary two stages of amplification at 10.7 mc. This requirement had led to a search for a low-level amplitude limiter. The most successful circuit of this type is the ratio-type detector.[8–9] Many of the f-m receivers and translators manufactured during 1947 and the first half of 1948 have made use of this detector. The advantages are several: (1) no limiter is required ahead of the ratio-type detector, (2) quieting is obtained with about one-tenth of the signal level needed to saturate a grid bias limiter, and (3) the side responses are low and with a well-designed ratio-type detector are quite narrow. Also the side responses are quite close to the main response. The result is a tuning characteristic which appears almost like a single response. The tuning characteristic plus the low noise level between stations give the ratio detector set an agreeable tuning action very similar to an a-m receiver. Although the ratio-type detector has found its principle application in low priced receivers, the linearity and noise reducing properties are sufficiently good to warrant its use in deluxe receivers.

The ratio-type detector has several disadvantages which have caused some manufacturers to continue the use of the grid-bias limiter and phase-shift discriminator. The output of the detector is low, particularly if only one stage of amplification at 10.7 mc precedes the detector driver stage. As a result many signals, sufficiently strong to produce quieting, do not produce enough audio output from the detector to properly drive the audio amplifier of the receiver. Another difficulty resulting from the low audio output is that hum introduced in the diodes of the discriminator proves much more annoying than is the case with the conventional phase-shift discriminator and limiter combination. To obtain good performance from a ratio-type detector, diodes having low internal resistance are required. Until very recently none of the duplex diode triode tubes had sufficiently good diodes for ratio-type detector use. Therefore an extra tube, a double diode, was needed. This offset, partially at least, the saving resulting from the use of the ratio-type detector circuit.

The Trend Towards Reduced Performance

The prewar f-m receivers, in general, were designed to maintain the standards of performance that had been set for f-m. Many of the early postwar receivers were designed with better-than-average audio systems and had excellent noise reducing capabilities. The high cost of a-m–f-m receivers compared to straight a-m sets has forced some sacrifice in performance even though the circuit improvements already described have resulted in considerable cost reduction. Audio range is logically the first to be sacrificed. First of all, most of the program material being broadcast does not make use of an extended audio-frequency response. Secondly, most of the public has not yet learned to appreciate true high fidelity. In fact, a restricted response range is more pleasing to many listeners. The audio systems of most of the a-m–f-m table models and many of the a-m–f-m console receivers built during 1947 and 1948 are no better than would have been used in a straight a-m receiver.

Most of the receivers now on the market exhibit reasonably good sensitivity and noise limiting ability. The necessity of getting away from the use of an outside dipole antenna has dictated against sensitivity reductions as drastic as the improved signal strengths might seem to permit. At least one manufacturer has marketed a table model receiver with no r-f stage on the f-m band. Reasonably good performance is obtained on local signals but the need for preselection and voltage gain at signal frequency make elimination of the r-f stage undesirable for most applications.

A particularly interesting answer to the search for a low-cost f-m receiver circuit is a form of super-regenerative[10] detector used in several receivers now on the market. In one tube, a double triode, this circuit accomplishes all of the func-

tions necessary to recover audio from the received carrier. The absolute sensitivity of this circuit is good, signals of less than 10 microvolts being audible. For reasonably quiet and distortion-free output, however, a signal of 200-to-300 microvolts is required. The circuit has no amplitude rejecting capabilities, being an a-m as well as an f-m detector. The sampling effect resulting from the fact that the detector is insensitive during the major portion of each quench cycle gives the circuit a measure of immunity from impulse noise.

The most serious disadvantage of the super-regenerative detector in its present form is interference with other receivers because of radiation. The most serious radiation is at signal frequency, since nearby receivers tuned to the same signal will be blocked completely or seriously disturbed. Strong radiation occurs at oscillator frequency also, as well as at a large number of other frequencies resulting from the combination of the oscillator, signal, and quench frequencies.

Although most exponents of f-m as a high quality service decry the advent of the inexpensive f-m receiver, a more practical viewpoint should be taken. If f-m broadcasting is to continue to grow, a large number of receivers must be placed in the hands of the public to provide the necessary listening audience. Since February 1948 programs of the large networks have been duplicated on affiliated f-m stations. The user of the low cost table f-m set will use the f-m band as a second broadcast band and, although none of the superior qualities of f-m may be exhibited by some of these receivers, the quality of reception on local signals should be acceptable. With the time on f-m stations made more attractive to advertisers the financial position of the f-m stations should improve enough to enable them to extend their services. In turn, the better service offered by the stations will attract more buyers of f-m sets.

Conclusions

At present only 129 fully licensed f-m stations are in operation.[11] These are the stations that have fulfilled all of the requirements of the FCC. Approximately 400 other stations are operating, most of them on limited schedules. In addition, construction permits have been granted for 783 stations and 86 applications are now pending with the FCC. Many of the stations are located to serve metropolitan areas. Millions of listeners are, therefore, included within the primary service areas of these stations.

The following production figures [2–12] show that the number of f-m set owners has steadily increased since the end of the war. During 1946, 181,045 f-m sets were produced. This number represented about 1.3 per cent of the total receiver production. In 1947 the number of f-m sets produced was 1,089,737 or 6 per cent of the total receiver production. During the first quarter of 1948, the 326,000 f-m sets produced represent 8 per cent of the output of all licensed manufacturers. Approximately 75 per cent of the 1947 f-m receiver output consisted of console-type receivers. During the first quarter of 1948 about 68 per cent of the f-m receivers made were consoles. The remainder of the receivers was made up of table model a-m–f-m combinations and f-m translators for use with standard receivers.

Although the trend is toward f-m receivers with reduced audio quality and reduced sensitivity, with many f-m receivers being produced that do not demonstrate the full advantages of f-m, many manufacturers are still producing receivers of the console type that are capable of demonstrating the superiority of f-m over a-m. These receivers plus the improved service that will accompany the growth of f-m broadcasting, might conceivably cause enough public interest in the noise freedom and high-fidelity of f-m to bring about an increased public demand for better quality receivers. Continued improvements in the art will bring high quality receivers within the reach of more of the public.

The high manufacturing cost of f-m receivers is at present one of the most serious obstacles to the progress of f-m. Even if an a-m–f-m receiver is cheapened and simplified to the point where the f-m band performance is no better than that of the a-m band, the selling price of the a-m–f-m combination table model is two to three times that of an equivalent quality receiver that has only the a-m band. The console-combination receivers do not reflect the cost of f-m as much as do table models since the chassis cost is a smaller proportionate part of the total receiver cost.

An additional factor impeding the progress of f-m that has not been discussed is the matter of television. The public in general has shown more interest in television than has been shown for f-m. At present most of the larger manufacturers are concentrating on television development and production, in an effort to meet the public demand for receivers. Presumably many potential receiver buyers are staying out of the market until television service is available in their area.

The bulk of the f-m receivers that now are in use were bought by the public in response to advertising and because most of the better quality console receivers that have been produced since the end of the war have incorporated the f-m band. The next few years will show whether or not the experience of the public will result in a continued demand for f-m receivers and broadcasting service.

Progress in Coaxial Telephone and Television Systems

L. G. ABRAHAM
MEMBER AIEE

THIS PAPER describes the coaxial system used in the Bell Telephone System to transmit telephone and television signals.

Development of the coaxial system was started some time ago, with systems working before the war between New York and Philadelphia and between Minneapolis, Minn., and Stevens Point, Wis. Various stages in the progress of this development have been described in previous papers[8,10] and the latest telephone terminal equipment has been recently described.[16] The present paper will outline how the system works and discuss some transmission problems, leaving a complete technical description for a number of later papers.

Figure 1 shows the coaxial routes which are now installed or which will be in service in 1948. There are about 5,000 route miles in service providing almost 3,000,000 miles of 2-way telephone circuits plus television network facilities. The entire program shown on the map for the next few years will roughly triple the route miles and more than triple the circuit miles. Miami, Fla., can now talk over coaxial systems across the continent to Los Angeles, Calif., (if they are on speaking terms), a distance of about 3,000 miles. It is also possible to talk from Albany, N. Y. to Charlotte, N. C. or from Buffalo, N. Y. to St. Louis, Mo., and by the middle of next year, it will be possible to talk from New York to Los Angeles via Chicago over coaxials.

There is a television network working from Boston, Mass. to Richmond, Va., a distance of about 600 miles, with radio relay from Boston to New York and coaxial for the remaining distance. There are dropping points at Philadelphia, Baltimore, and Washington in addition to the terminals. There is a midwestern television network for service this fall to connect St. Louis, Chicago, Toledo, Cleveland, and Buffalo by coaxials with Milwaukee, Detroit, and other points along the route connected in by radio relay. Early in 1949, it is expected that these two networks will be connected together by coaxial cable from Philadelphia to Cleveland via Pittsburgh, with a maximum television circuit distance of about 1,500 miles.

The *L1* coaxial system is capable of transmitting, on two coaxials and their associated equipments, 600 telephone circuits or alternatively a 2-way television circuit 2.8 megacycles wide. This system has presented a number of difficult technical problems. The step from the older cable carrier systems having 12 channels to a system with 600 channels was a large one and television transmission introduced additional requirements over telephone transmission. The total cable loss for a 4,000-mile circuit is about 27,000 decibels at the top of the transmitted band and about 4,000 decibels at the bottom, thus requiring large amounts of gain and gain equalization. But large numbers of systems are now working and the solutions to remaining problems seem foreseeable or in hand.

General Arrangements

Types of Cable. In the coaxials made before the war, the inside diameter of the outer conductor was 0.27 inch. The diameter of the inner conductor was 0.072 inch. Hard rubber disks spaced about 3/4 inch apart separated the inner and outer conductors. The outer conductor was 10-mils thick with a longitudinal seam. Over the outer conductor were two steel tapes applied helically along the coaxial, the second tape overlapping the gap between successive turns of the first. Experimental sections were installed before the war with polyethylene disks used rather than the hard rubber disks, because of their lower losses at high frequencies and since the war polyethylene disks only have been used.

The cable now being made is all about 40 per cent larger with an inside diameter of the outer conductor of 0.37 inch,[13] with an inner conductor diameter of 0.10 inch and with a thickness of the outer conductor of 12 mils. The polyethylene disks are spaced about 1 inch apart, but in general design it is identical with the smaller coaxial. A typical arrangement of the eight coaxials of this type in a lead-covered cable, with the associated service pairs and other conductors is shown in reference 15.

These cables are generally buried directly in the ground or in ducts, both for protection and to reduce the amount of temperature variation which would tend to make quite difficult equalization of these cable systems to the precisions desired. Typical attenuation and impedance of the 0.37-inch coaxial cables are also shown in reference 15.

Since only the 0.37-inch coaxials are being installed now, the remainder of the paper will consider only this size, with repeater spacings, and so forth, being given only for the larger coaxials. In general, the 0.27-inch coaxial spacings are less than the 0.37-inch coaxial spacings, with certain spacings limited by power feed to half those of the larger coaxials.

Layout. The line of the coaxial cable system consists of the cable plus main repeater stations at fairly wide intervals with auxiliary repeater stations between them at much closer intervals. The main repeaters are separated by varying distances, depending upon the points at

Paper 48-273, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted August 9, 1948; made available for printing September 9, 1948.

L. G. ABRAHAM is with the Bell Telephone Laboratories, Inc., New York, N. Y.

which it is desired to drop circuits and upon other factors. The maximum distance between main repeater stations is about 165 miles, being limited by the maximum voltage at which it is practicable to feed power from the main repeaters to the auxiliary repeater stations. The average distance is 105 miles, with a minimum distance of about 40 miles.

The auxiliary repeaters are spaced at approximately 7.9 miles, the precise spacings depending upon the average temperature of the region and, of course, upon practical problems of putting the repeater points at accessible locations. The auxiliary repeater stations are usually concrete block huts[13] without heat, power, or light, except the repeater power supplied over the centers of the coaxials. In rare cases, they may be in existing buildings or in manholes where a separate building is not practicable, as in large cities. The main repeater stations are typical Bell System buildings with electricity, reserve battery supply, testing means and heat, although these will often be unattended also.

The main repeater stations may be either switching or nonswitching stations as will be explained later. The average switching section is about 110 miles.

Dropping and branching points[16] are places where telephone or television circuits are dropped, where some of the telephone circuits take different routes from others or where a television circuit goes in more than one direction. These are always at switching points to insure continuity of service when switches occur. The general layout of such a station when it is a television dropping point will be described later.

About every 800 miles along present coaxial telephone systems, all the coaxial lines are brought down to supergroup frequencies, group frequencies, or voice frequencies. It is thus possible to adjust the equalization of the high-frequency line and to rearrange the supergroups or groups as required to avoid excessive modulation. These points also provide patching means for flexibility purposes where any group of 60 circuits may be patched to any direction and in any combination of supergroups.

Outline of Functions. Figure 2 shows a simplified schematic of the main parts of a high-frequency line. At the left in a terminal station is a telephone or television terminal. Next in the upper part is a box marked *DE*, which would be delay equalizers on a television line or might be merely a pad on a telephone line. Next is a hybrid coil which divides transmission between the working line and the spare line. The transmitting amplifier *T* raises the level of the signals for transmission into the coaxial cable.

Finally, power separation filters *P* are used which are designed to enable the 60-cycle a-c power for the auxiliary stations to be applied to the centers of adjacent coaxials without interfering with the high-frequency circuit. This power feed is a series power feed, that is, there is substantially constant current throughout the line at all points, with the voltage to ground therefore decreasing as the distance from the power feed point increases. Of course, in a system with capacitance to ground, the power line current would not be quite constant because of the shunt currents, and systems would be limited when the current had dropped too much to permit adjusting the auxiliary repeater to obtain the proper voltages. A power loading system is used which effectively loads the power circuit after it has been taken off the line at auxiliary repeater points and this permits power to be fed over the distance mentioned before.

The next box on Figure 2 shows the layout of an auxiliary repeater. The power separation filters take the power current off the line and through a series transformer winding. There are adjustments for minor residual variations in the line current and to allow for aging in the selenium rectifiers used to produce *B* supply for the amplifiers and regulators. The basic equalizer *E* and the amplifier *A*

Figure 1. Coaxial cable and radio relay routes of the Bell Telephone System

Figure 2. Schematic layout of a coaxial system

together correct for the line loss in the preceding cable section over the band from 60 kc to 3.1 megacycles. At the amplifier output is bridged a pilot regulator R_1 which measures a 2,064-kc pilot sent over the line and adjusts the amplifier gain to keep the pilot level constant by changing the resistance of a thermistor in the amplifier beta circuit. At approximately every other auxiliary repeater point, a manual regulator is used which does not measure the 2,064-kc pilot, but holds the amplifier gain at a value the maintenance man sets by manual adjustment. Changes in loss of the manually regulated section are taken up by the pilot regulator at the next station. The manual regulators are cheaper than pilot regulators, require very little maintenance as units, and reduce the total number of pilot regulators in tandem with advantages discussed later.

Figure 3 shows an auxiliary repeater in its apparatus case. These apparatus cases are hermetically sealed and desiccant is included in the box to avoid possible effects of moisture condensing in the case when the temperature decreases. This sealed case is essential where the case is in a manhole which might be filled with water and in all cases avoids possible effects of excessive moisture on gain characteristics and damage from rodents and insects.

The regulators, amplifiers, power transformer, power separation filters (PSF) and power loading units are indicated. Between the amplifiers are jacks and testing means. The power separation filters have monitoring jacks for test purposes. When a pilot regulator is used, rectified current from the pilot flows through a relay in the pilot alarm unit (below the power transformer) holding it at the center point of its range. If the pilot should go down considerably or become much too high, the pilot alarm unit will put a short across the pilot alarm pair, thus bringing in a signal at the nearest main repeater station which can then be investigated by the attendant at that station. Below the main panel at some points are other panels which vary from point to point. On these are placed power loading coils, building out line sections, and so forth, as required. In the center at the bottom are the four connections between the panel and the lead covered cable.

In addition to the auxiliary repeater boxes, each auxiliary station has a box containing a small cross connection frame for the pilot alarm pairs and the order wire, a telephone set, and so forth. The order wire is used by the maintenance man to call in to an attended repeater station and get help of various kinds as required. The regulators, amplifiers, and pilot alarm units plug in, so they may readily be removed for maintenance purposes.

As may be seen from Figure 2, the nonswitching main repeater station has input and output circuits very similar to those at the auxiliary station or the terminal station. The power separation filters connecting to the power supply come first. Next, is a basic equalizer (E) as at the auxiliary point and then a receiving amplifier (R). This amplifier is very similar to the auxiliary amplifier except that its output is adjusted to have a good 75-ohm impedance instead of the variable impedance used at the auxiliary station to improve the signal-to-noise ratio. After the receiving amplifier is the "A" equalizer. This equalizer is controlled by three additional pilots sent over the line at 64, 556, and 3,096 kc. In each case, a regulator measures the amount of power at these frequencies and adjusts certain loss shapes in the "A" equalizer to keep the over-all gain constant at nearby frequencies. There are also a considerable number of manual adjustments of the loss which may be used to correct for differences between main repeater sections due to length and due to the particular amplifiers and repeater panels in that section.

At the output of the "A" equalizer at switching main stations is a flat gain amplifier to bring the level of the telephone or television channels back up to normal. In most cases, the flat gain amplifier and delay equalizer will be omitted at nonswitching main stations. At the switching main station, there may also be a "B" equalizer and another flat gain amplifier. These are placed at intervals to mop up residual gain variations. At the output of the flat gain amplifier are the pilot indicators. At each of the four pilot frequencies, a filter picks off the particular pilot and an amplifier rectifier shows the level at that point on a meter so that in case of trouble it is possible at a glance to see whether the trouble is located in a particular frequency region.

Switching main repeater stations as in the next box to the right on Figure 2 are very similar to nonswitching main repeater stations except for the fact that they are switching points. The present switching system provides for automatic switching of the spare line to replace one working line and manual patches may be made to replace other working lines.

Figure 4 pictures a typical layout of apparatus at a switching main station. A dropping or branching point such as shown at the extreme right on Figure 2 is always a switching point. A given television picture or a given group of 600 telephone channels will always appear in a common part of the circuit at a given switching main repeater station, although at any given time it may be passing over any one of several coaxial lines at intermediate points. In the telephone circuit case, there may be band elimination filters in the common part to suppress certain frequency ranges, thus permitting use of a given frequency range on both sides of the office. There are also similar arrangements to permit dropping sound program circuits as required.

Figure 3 (left). Auxiliary coaxial repeater

Figure 4 (right). Main coaxial repeater station

Figure 5 shows typical dropping arrangements on a television circuit. The television signals come in from the coaxial cable through the receiving amplifier, equalizers, flat gain amplifier *F* and the switching circuit. Next is a hybrid coil *H* which permits through transmission to go on while a local connection is bridged. The through circuit passes through coaxial television switching equipment *TV. SW.* to equipment *D. E.* which provides delay equalization for the succeeding line. The coaxial television switching equipment may be used to change this point from a bridged dropping point to an originating picture point.

The bridged receiving equipment is self-explanatory. Adjustable equalizers for the local picture which do not affect through transmission may be needed as shown. On the transmitting side, pilot supply to provide the four line pilots is necessary when those from the line on the left are interrupted by the *TV. SW.*

The method of operation of the television terminal was described in reference 10 and is still essentially the same except that there is now a 556-kc line pilot which is eliminated at the receiving end in the same way as are the 2,064 and 3,096-kc pilots. This terminal uses vestigial sideband transmission with a carrier at 311 kc, the vestigial sideband extending down to about 200 kc. The sound program terminal[18] is essentially the same as that used for program transmission over other wide band systems. It transmits the sound by single sideband in the range between 80 and 88 kc.

Maintenance Method. The maintenance of coaxial systems is somewhat different from that of previous cable systems. The general philosophy is to merely check circuit performance at the many amplifier points and to return suspected apparatus to more central points for complete testing. The auxiliary stations do not contain testing equipment of any kind. They are maintained by a man who generally covers somewhat less than 200 miles of line by visiting the auxiliary stations on a routine basis or in case of trouble. The repeaters are tested and doubtful equipment removed and replaced with new equipment. The removed equipment is then returned for further tests at a main station called a regulator maintenance point. These points are roughly 150 miles apart along coaxial systems. The three bays at the left of Figure 6 comprise the testing equipment. This is used to test and repair regulators, pilot alarm units, repeater panels, and miscellaneous small items. In addition, amplifiers can be tested approximately by this equipment but are not repaired from these tests. In case an amplifier seems to need to be repaired, it is shipped to an amplifier maintenance point, often many miles away, as there are only five such maintenance point scattered over the country at present.

In the case of Figure 6, the amplifier maintenance point is in the same room and comprises all the other equipment shown. At these points, amplifiers are first opened since they are hermetically sealed, the older ones being soldered, but the newer ones using a pressure seal. The gain characteristics are measured with great precision in a recording gain set. There are various other items of testing equipment permitting precise checking of vacuum tubes, measuring modulation, adjusting impedances, and making various adjustments. After repair, the amplifiers are again sealed and returned for service use.

Portable measuring equipment is taken by the maintenance man to the auxiliary points in a truck. The power meter when plugged into the auxiliary panel permits measurement of all the essential power voltages. The portable pilot indicator may be plugged in to measure the power of the 2,064-kc pilot at the output of the amplifier and to allow small adjustments as required in the regulator sensitivity or in the manual regulator setting. The transmission measuring set is a tuned detector which may be used to measure at

Figure 5. Schematic layout of television dropping arrangements

Figure 6 (right). Regulator maintenance equipment and amplifier maintenance equipment

the input or output of the amplifier. Other equipment available in the truck includes an oscillator which supplies any one of five frequencies and is used in combination with the transmission measuring set for cable measurements when trouble is suspected there. There is also equipment to measure the modulation products of the amplifier in place and miscellaneous items used at rare intervals.

When trouble is indicated, the man at the auxiliary station may call an attended point and have the spare line in that direction switched to include the particular repeater, thus allowing the amplifier or regulator to be changed. If the panel has to be changed, not only must both of the lines be made spare but also the power on the center conductors must be turned down to avoid possible danger and damage.

At the main station, the testing equipment items are larger although they are commonly mounted on racks equipped with wheels so that they may be moved from place to place. The main items are:

1. An oscillator supplying any frequency from about 50 kc to 3.5 megacycles.

2. An analyzer, old or new models of a tuned detector with which it is possible to measure at any frequency from 50 kc to 3.5 megacycles at powers down to about −110 decibels below one milliwatt. It is also used to make line modulation measurements.

3. The transmission measuring set, really a sensitive thermocouple which permits measurements at any frequency over the band without tuning. In order to avoid interference from the line pilots when this measurement is made, it is necessary to have the power at the testing frequency considerably larger than the power of the pilots.

4. The thermocouple meter, used to calibrate the power sensitivity of various items of testing equipment. The calibration essentially depends upon the accuracy of a meter and an impedance. Direct current from a battery is used to adjust its sensitivity, and the sensitivity of the other equipment such as the analyzer is compared to that calibration.

At the main station, it is also possible to determine the auxiliary repeater station from which alarms are received. This is essentially a d-c bridge measurement of the resistance of the pilot alarm pair to the point at which a short is applied when an alarm is given. It is also possible to release temporarily the alarm relay at the auxiliary point and if the trouble has cleared, it is thus set for future action.

It has been found practicable to station men permanently only at occasional main repeater stations, if they are not needed for other local work. In order to be sure that trouble will not ensue from this, a special control system has been devised. This is a system which, at an unmanned main repeater station, continuously inspects a large number of circuit functions and returns an alarm to the nearest attended station if anything performs unsatisfactorily. When an alarm has been returned, the attendant at the distant station may request information from the unattended station which is then furnished in some very considerable detail, there being about 150 separate indications of what is going on at the unattended station. It is also possible for the attendant at the distant station to direct certain actions to be taken at the unattended station, such as switching a particular working line to the spare line, and so forth. By the use of this system, there are cases in which 24-hour main repeater station attendance is required only at wide intervals up to 650 miles.

At television terminals, there is special testing equipment designed to be used to test the television equipment. Primarily, this consists of a transmission measuring set and oscillator which are able to test up to the 8-megacycle carrier used at the television terminal. It also comprises monitors and "A" oscilloscopes for testing television pictures directly, and associated apparatus such as a 311-kc oscillator to supply this frequency as a carrier when a television signal is not available, a looping filter for connecting a transmitting terminal directly to a receiving terminal, and so forth.

Security. Very great care is taken in the design of this system to avoid failure of service. As discussed before, the cable is usually placed underground where it is less susceptible to damage and every care is taken to avoid losing a cable due to natural events. For example, in crossing a known earthquake fault, the cable is coiled back and forth in a bed of gravel so that considerable movement may take place without breaking the cable. As another example, in crossing large rivers, there are commonly two submarine cables placed over somewhat different crossings and half the coaxials are routed through one cable and half through the other, with sufficient capacity in either cable to carry the entire group of coaxials if necessary.

The power supply is designed to be reliable. The load of supplying 60-cycle power will automatically fall back on storage batteries at the main repeater station if commercial power fails. Some systems use rectifier-inverters which electronically generate 60 cycles from the direct current of the storage batteries. In the newer systems, motor-generator sets are used which run from commercial power normally, but with power to the coaxial line supplied from a generator mechanically coupled to the a-c motor rather than directly from the commercial power supply. In case the commercial power fails, a d-c motor which is rotating on the same shaft is automatically connected to the storage battery and drives the a-c generator without substantial loss in time or voltage. This scheme avoids various effects of commercial power variation and superimposed noise in some sections.

The amplifiers are all equipped with parallel tubes and one tube in any or all stages could fail without causing any substantial detriment to the circuit as a whole. The spare line, of course, also allows for a complete amplifier or coaxial failure, being

switched in automatically when the working line fails, without substantial interruption to any service. There are, of course, gas pressure alarms on the cables which come in if there is any substantial leak in the sheath, alarms as described before at each auxiliary station if the pilot levels should go out of limits either on the high side or the low side and alarms of many kinds at unattended main stations to indicate potential trouble at these points. Of course, the security of any such system finally is determined by the goodness of the design of the equipment, by the quality of manufacture, and the excellence of the maintenance which finds potential trouble before it can affect service.

Transmission Problems

Coaxial systems are designed to give satisfactory telephone or television circuits for up to 4,000 miles. This comprises about 500 repeaters in tandem or approximately 250 regulators. In order to make this system satisfactory for such lengths, very considerable design advances have been necessary.

Regulation. Figure 7 shows schematically the layout of a regulator to measure the 2,064-kc pilot and adjust the gain of the amplifier to hold the output level constant. 2,064 kc is picked off by the crystal pilot pickoff filter *P. P. F.* bridged across the line and is amplified and rectified as shown. The amount of direct current at the point marked determines the output of a 2-kc oscillator and part goes to a pilot alarm unit *P. A.* which gives an alarm if the pilot level deviates too much. The oscillator output is fed into a thermistor *T* in the beta circuit of the amplifier. The amount of 2,000-cycle current determines the amount of heat in the heater of this thermistor, controlling the temperature and therefore the resistance of the thermistor, and the resistance of the thermistor determines the gain of the amplifier. Changes in amplifier gain follow a square root of frequency characteristic over the band from about 50 kc to 3.1 megacycles.

The combination of the amplifier and regulator comprises a feed-back circuit at very low frequencies and if the phase of the feed-back circuit became too great at any frequency at which there was gain around the path, singing or "hunting" might occur. The principles of feed-back design were applied to the circuit, and equipment for measuring such a circuit was devised. The practical difficulties may be appreciated when it is pointed out that the frequencies of interest are from 0.01 cycle or less to at least 100 cycles.

With good individual stabilities, the matter of tandem instability had to be considered. When there is a sudden small change in pilot level near the sending end of a long circuit equipped with dynamic regulators, a much greater change may be obtained temporarily at the receiving end of the circuit, such as is shown in Figure 8. Such regulators are said to have tandem instability. In general, long circuits equipped with such regulators will also have "jitter," which is indicated by continuous random and erratic variations in the received pilot. This is due to an accumulation of many very small fluctuations in gain, presumably because of 60-cycle power changes.

The amount of tandem instability depends upon the gain around the local feed-back path in each regulator, as well as its phase, and therefore varies with the length of the repeater section and the temperature of the cable as well as the adjustment of the regulator and other factors. The regulators now being produced are satisfactory for all present telephone and television circuits and for those contemplated in the near future. Very long television circuits will require further advances from this standpoint, such as pilot suppression and resupply at wide intervals or other means.

Gain Equalization. On a 4,000-mile circuit there will be, say 500 repeaters in tandem, making up for a loss of about 27,000 decibels at 3 megacycles and about 4,000 decibels at 60 kc. On a television circuit we might take ±1 decibel as the allowable variation from flat gain in the over-all circuit over the range from 200 kc to 3.1 megacycles. Of course, the true objective is much more complicated than this, varying with the frequency and so forth, but this will serve to illustrate the problem. To obtain this accuracy by making each repeater sufficiently precise, the average gain per auxiliary repeater section would have to be kept flat within ±0.002 decibel. For telephone circuits, considerably wider limits on the high-frequency line gain are possible because of the intermediate and terminal points where the gain of groups, supergroups or individual channels can be adjusted separately based on measurements of the over-all system.

It is not practicable to manufacture repeaters to any such accuracy as a few thousandths of a decibel and too many elements would be required for a design with this accuracy. The gain cannot even be measured to such accuracies. The sources of deviations from the desired characteristics and the shapes of such deviations versus frequency can be studied. Element values can be controlled and measurements can be made as accurately as possible, but when all this is done, one repeater section can still be checked only very unprecisely. What can be done is to put a number of repeater sections in tandem and measure them. This reduces the measured error per repeater section by a divisor equal to the number of such sections measured. By this means, the average characteristics of the repeaters and of the basic equalizers which go to make up the over-all characteristics of the auxiliary repeater sections and of the main repeater sections can be determined. From this information, "A" equalizers for the main stations can be designed. A considerable number of such main sections equipped with "A" equalizers can be measured and "B" equalizers specified to mop up the deviations of a few hundred miles.

In manufacture by the Western Electric Company, the amplifiers are held to roughly ±0.25 decibels over the frequency range of interest. At one time, comparison with reference amplifiers was used to determine that the desired gain characteristics were obtained. But these reference amplifiers aged and changed in gain characteristic so that it was a never-ending struggle to keep them alike and with the proper characteristics to the necessary precision.

The so-called absolute gain standard has been adopted where each amplifier is measured on an absolute basis in a panel which is controlled to have very nearly the impedance and losses of an average field repeater panel plus the preceding line section. The control of impedance is essential because the auxiliary repeater panel impedance does not match the line impedance, particularly at high frequencies. This was intentional in the design and very substantial advantages in signal-to-noise ratio for a given repeater spacing were obtained in this way. But, it did make the gain sensitive to the impedances in which the amplifier was measured.

Other changes have been made in the amplifiers to reduce variations in their gain characteristics with time and between amplifiers. These variations were very small individually, being a few hundredths or at the worst tenths of a decibel per repeater section over a 3-megacycle band. Nevertheless, they were of considerable importance in planning 500 amplifiers in tandem with the over-all precisions necessary for television transmission. The sources of such variations have been located and changes made to reduce them to negligible proportions.

Figure 7. Schematic layout of a regulator and amplifier

They consisted mainly of stray capacitance couplings which affected feed-back paths or phase margins by small amounts.

Phase and Delay Equalization. Phase and delay characteristics of wide band systems are not particularly important on telephone circuits because only about 3,500 cycles in one piece is of any importance. On television circuits, however phase equalization is just as important as gain equalization. In fact, the same magnitude of picture ghosts can be produced by gain or phase deviations, equating 1 decibel to about 7 degrees.

Of course, difficulties with amplifiers as to gain equalization also cause difficulties with phase and delay equalization. Also, such variations in gain tend to confuse the issue as to data on delay characteristics, but as the amplifiers are stabilized, the delay characteristics become more manageable.

The basic phase distortion may be correlated with the band-pass gain characteristics of the television circuit. This system appears to be substantially a minimum phase system, that is, the phase distortion characteristic could be predicted rather precisely if the gain characteristic from zero frequency to infinite frequency were known. Unfortunately, the gain characteristic cannot be measured far enough down into the high loss region at either end of the transmitted band, so the phase or delay distortion must be measured separately.

Figure 8. Variation of 2,064-kc pilot and end of circuit due to 0.1 decibel step at input

Large blocks of delay equalizers are inserted at intervals along the line to approximately compensate for the delay distortion of the succeeding line section. To keep the number of types of such blocks at a minimum, delay building out networks are used to build out the delay of the particular delay section by amounts up to two auxiliary repeater sections, and this also provides some adjustment for differences between sections and for changes of the line with time and temperature.

Noise and Modulation. Any telephone or television system must have a satisfactory signal-to-noise ratio and must be free of excessive modulation. From a noise standpoint, the present coaxial system seems generally satisfactory. Certain sources of 60-cycle power noise have had to be cleaned up, but otherwise the measured results just about fit the design values as expected. Of course, such noise can be controlled by varying the repeater spacing. Figure 9 shows typical noise on a 200-mile circuit. It may be seen that the noise is fairly constant with frequency up to about 2 megacycles and then increases. Television circuits can tolerate much more noise at such high frequencies and the few telephone circuits above 2 megacycles are used only for short distances, so the higher noise there is not objectionable.

Modulation is a tougher nut to crack. There are innumerable modulation products to consider. For example, each telephone channel A modulates with every other telephone channel B, producing $A \pm B$, $2A \pm B$, and so forth, products, many of which fall into some other channel and may cause objectionable noise or crosstalk. Each of the pilots which control the gain characteristics will modulate in various ways with each of the telephone channels, with other pilots and with carrier leaks. In the case of television circuits, the pilots all modulate with the television signal, particularly with the carrier at 311 kc. The 311-kc carrier produces in the line second, third, fourth, and up, order harmonics and other products.

Figure 9. Noise at the −10 decibel level point on a 200-mile coaxial circuit

The modulation products add in various ways as the length of line increases, accumulating different modulation products from each amplifier. Typically, the $A \pm B$ products, for example, which are produced in different amplifiers, will be somewhat out of phase relative to the products in previous amplifiers so the successive products will add in a somewhat random manner or roughly as the sum of their power ratios. Some of the products, notably the $2A$-B products, may have very little, if any relative delay difference between the two modulating frequencies and the product created at the previous amplifier, so successive sections may tend to add directly or as the sum of the currents. On television lines which are phase equalized, this tendency will be even greater.

Most modulation products could be improved by reducing the level of the signals at the expense, of course, of a poor signal-to-noise ratio due to tube noise and resistance noise. For example, in a simple cube law amplifier, if the television signal were reduced to 1 decibel, its second harmonic will be reduced 2 decibels which is 1 decibel relative to the signal. The third harmonic will decrease 3 decibels or 2 decibels relative to the signal, and so forth. For modulation products of, say, telephone signals against any fixed tone such as the pilots, however, such an improvement cannot be obtained. For example, the second order products decrease 1 decibel when the signal is reduced 1 decibel, but this gives no net advantage in the ratio of modulation products to the signal. A third order product of a frequency twice the pilot minus the signal will also not be improved when the signal is reduced.

It seems pretty clear that telephone service over our longest coaxial systems will be satisfactory from a modulation and noise standpoint, since 3,000-mile systems equipped with a considerable number of circuits are already giving satisfactory service. On television circuits, there is

not enough data as yet to be sure. Certain improvements which can be made in the television terminals to give improvements in modulation products for a given signal-to-noise ratio make it seem likely that commercial television pictures can eventually be transmitted across the entire country by coaxial systems.

No Discussion

Bridge Erosion in Electrical Contacts and Its Prevention

W. G. PFANN
NONMEMBER AIEE

ALTHOUGH the more severe forms of erosion in electrical contacts are due to electrical discharges, some damage is caused in d-c circuits by the molten bridge which exists momentarily between two contacts as they separate. Bridge erosion predominates in contacts of low-voltage circuits having little inductance and it generally produces a spike on the negative contact and a closely fitting crater in the positive contact. Although the transfer may be quantitatively small, locking or premature closure may result, especially if the contact force is low or the contact gap is short. Noble metals and their alloys are particularly prone to this form of erosion.

Attention was called to the molten bridge as a source of material transfer in electrical contacts by Betteridge and Laird.[1] The physics of the molten bridge and data on the transfer attributed to the molten bridge are discussed by Fairweather,[2] by Holm,[3] and in a recent comprehensive study by Lander and Germer.[4]

This paper describes a correlation between the shape of the molten bridge and the transfer of material accompanying its formation and rupture. It is shown that such transfer can be prevented in electrical contacts operated under conditions in which bridge erosion is stronger than, or comparable to other transfer processes. The method involves the use of dissimilar materials in the contact pair and has so far been tried principally with noble metals, but with certain restrictions it should be applicable to base metals. The experimental work which led to this finding will be described briefly and the conditions for preventing bridge erosion will be given in some detail.

Paper 48-274, recommended by the AIEE basic sciences committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted July 8, 1948; made available for printing September 15, 1948.

W. G. PFANN is with the Bell Telephone Laboratories, Inc., Murray Hill, N. J.

The author is indebted to J. H. Scaff for many helpful discussions during this investigation.

Testing Conditions

The testing circuit was essentially a series arrangement of a source of voltage, a resistive load, and the contacts. Inductance and capacitance were reduced to small values in order to minimize the dissipation of energy at the contacts on break and make respectively. The inductance of the battery leads was effectively eliminated by placing capacitors across the leads at a position physically close to the contacts, as shown in Figure 1. The inductance of the remainder of the circuit, loop *abcd*, was 3×10^{-7} henry and the distributed capacity of *abcd* measured at the contacts was 8×10^{-13} farad. C_2 was in effect a short circuit at the resonant frequency of the loop, which was about 100 megacycles.

The contacts were operated mechanically, as shown in Figure 2. The moving contact arm was pivoted at one end and actuated by a cam at the other. The arm rested on the rotating cam for a half revolution and on the fixed contact for the remaining half. The static contact force was the portion of the weight of the arm borne by the lower contact. The test contacts were cylinders 0.125 inch long and 0.050 inch in diameter and were held by clamps which permitted easy removal for weighing. Contact was made between slightly rounded, metallographically polished end faces.

Precautions were taken to prevent undesirable mechanical effects. Chatter on the make was nullified by means of a butyl rubber pad beneath the fixed contact clamp. Horizontal play, which might have caused wiping was minimized by using tightly-fitting pivot bearings for the pivot shaft of the moving arm. Vibrations from the motor were blocked by suspending the motor on rubber mountings and driving the cam shaft through a sponge rubber fitting.

Unless otherwise indicated all tests were performed under the following conditions:

1. Battery voltage, 6.3 volts.
2. Steady current, 5.3 amperes.
3. Number of operations, 85,000.
4. Operation, make and break.
5. Frequency, 4 cycles per second.
6. Static contact force, 100 grams.
7. Atmosphere, room air.

Emphasis was placed on noble contact metals and alloys because of their importance in communications equipment. Among the materials which were studied are:

Platinum
Palladium
Gold
Silver
Platinum—iridium alloys
Palladium—silver alloys
Palladium—gold alloys
Palladium 60—copper 40
Gold 70—silver 30
Gold 69—silver 25—platinum 6
Gold 95—nickel 5

Base metals such as copper or nickel could not be operated at low contact forces under these test conditions, as oxidation at the high temperatures of the molten bridge soon resulted in open circuits.

Experimental Findings

The Molten Bridge

The formation and rupture of a molten metallic bridge between separating contacts are described here because much of what follows pertains to measurements on the remains of such bridges in the areas of erosion. This picture is based upon results of earlier investigators,[1–3] upon a recent detailed study by Lander and Ger-

Figure 1. Testing circuit. $C_1 = 375$ microfarads. $C_2 = 0.1$ microfarad (mica)

mer,[4] and upon the writer's microscopic observations of ruptured bridges.

Consider two separating contacts: As the force is released the area of contact decreases; the resistance, and hence the temperature rises. Melting occurs at the interface, and liquid metal bridges the gap between the separating contacts. Further separation increases the resistance of the bridge until its temperature rises to the boiling point, whereupon a semi-explosive evolution of vapor blows the liquid metal into an irregular ridge about the base of the bridge in each contact. Figure 3 show stages in this process. At the instant of break the potential difference across the bridge is on the order of one volt.

Each explosion leaves two smooth, shallow pits, one in each contact, as shown in Figure 4. The eroded areas of both contacts become covered with these pits after many operations. The diameters of such pits have been carefully measured at high magnification and are the "bridge diameters" to which reference will be made later. An area typical of those in which such measurements have been made is shown in Figure 5.

Bridge Diameters

The diameter of the molten bridge increases linearly with current. Data for platinum contacts are shown in Figure 6. The plotted diameters are means of from 12 to 20 observations on both contacts. The bridge diameters in the two contacts were equal at all currents except 0.8 ampere.

The diameter of the molten bridge depends upon the contact material. Some values are shown in Table I. The figures are means of observations on both contacts.

The materials are listed in order of decreasing bridge diameter, which is also approximately the order of their resistivities at room temperature.

Although some metals form bridges which have equal diameters in the two contacts, in other cases the bridge may be asymmetric, and the diameters in the two contacts may differ considerably. Platinum is an example of the former; silver of the latter. In all like pairs which were examined and which showed asymmetry, the larger diameter was in the positive contact. Some values are listed in Table II. The asymmetry factor, f, is the ratio of the bridge diameter in the positive contact to that in the negative.

Asymmetry occurs only in the smaller bridges. Silver exhibits the greatest asymmetry and also has the smallest mean bridge diameter. If the bridge diameter is reduced by lowering the current, asymmetry appears for metals which bridge symmetrically at 5.3 amperes. For example, platinum, palladium, and palladium-silver alloys form asymmetric bridges at 0.80 ampere. Apparently the effect is masked in the larger bridges.

Transfer Tests

In every case material was transferred to the negative contact with negligible net loss. Buildup and crater fitted almost exactly. Anode losses varied from about 5×10^{-6} to 100×10^{-6} grams.

Transfer occurred only in separating contacts; under these conditions the erosion during closure was negligible.

The quantity transferred varies approximately as the third power of the current at currents in the neighborhood of 5 amperes.

The fraction of the volume of the bridge which is transferred to the negative contact at each operation is greater for asymmetric bridges than for symmetric ones. Bridge volumes were estimated from measured bridge diameters. The volume of metal transferred per operation was obtained from the transfer tests.

Analysis of Results

The data indicate that contact materials may be divided into two classes, symmetric and asymmetric, according to the form of the bridge and that greater transfer is shown by the asymmetric class. This suggests that at least two actions may cause transfer under these conditions, as the following analysis indicates.

Transfer of the first kind is apparent in metals which form symmetric bridges. Because the bridge is symmetric, one might expect that statistically each contact would contribute metal equally to the growing bridge and that upon rupture of the bridge, the scattered metal would divide equally between the two contacts. However, since transfer is observed, its origin is presumably unrelated to bridge shape. Erosion of this kind will be called A transfer. It was later found to be at least partly due to the discharge of inductive energy stored in loop *abcd* (see Figure 1) but this will not be discussed here. Under these test conditions, the

Figure 6. Diameter of molten bridge as a function of steady current for platinum contacts. Battery voltage—6.3

direction of A was always toward the negative.

The increased erosion observed for metals which form asymmetric bridges suggests that a transfer tendency which is related to the unbalanced form of the bridge reinforces A. Erosion due to this condition will be called B, or asymmetry transfer. Presumably the contact which has the larger bridge diameter contributes more metal to the bridge than does its mate, and then suffers a net loss in the division of the molten metal upon explosion of the bridge. Since for all like pairs showing asymmetry, the large bridge diameter has been in the positive contact, the directions of A and B have been the same.

To summarize, the data suggest that two kinds of transfer action may exist under these test conditions:

1. A, the direction of which is always toward the negative.

2. B, which is the result of asymmetry in the molten bridge. Its direction is away from the metal of large bridge diameter, and its magnitude increases with the degree of asymmetry.

Having postulated these two transfer actions, it became of interest to consider means of varying one of them independently. This led to the idea of creating an artificial asymmetry in the molten bridge by pairing metals having different natural bridge diameters. (By natural diameter is meant the bridge diameter when both contacts are of the same metal.) Since the sense of the asymmetry could be reversed by interchanging the contacts, B could be made either to oppose or to support A.

The erosion to be expected for such a combination will be discussed, assuming platinum and gold as the two metals. Platinum has the larger natural bridge diameter and forms symmetric bridges; gold has a natural asymmetry which may be disregarded here. In Figure 7 the shapes of the molten bridge are shown schematically and the direction and magnitude of A and B are represented by vectors for both arrangements of the contacts. According to the analysis the erosion will be as follows:

Case I. *Platinum* (+), *Gold* (−): Since platinum has the larger bridge diameter, A and B act in the same direction, and transfer begins toward the negative at a high rate, as shown in Figure 7 (*a*). As the layer of platinum builds up on the negative contact, that contact becomes more like platinum. Hence the bridge diameter in the negative gradually increases until at some layer thickness the underlying gold no longer has an effect and the bridge diameter attains the value for platinum. This situation is shown in (*b*). The asymmetry has disappeared and transfer toward the negative continues at the normal rate for platinum.

Case II. *Gold* (+), *Platinum* (−): A and B are opposed, because the larger bridge diameter is now in the negative contact, as shown in (*c*). Since B has been taken greater than A, transfer begins toward the gold contact. Notice that the direction of transfer is now toward the positive. The layer of platinum on the gold contact causes an increase in bridge diameter in that contact. Hence B decreases, because of the reduction in asymmetry, until it becomes equal to A, as shown in (*d*). This is the equilibrium condition for the system. No further transfer occurs.

If in some way a thicker layer of platinum had formed on the gold, the bridge asymmetry would then be so small that B would be less than A as shown in (*e*). A transfer of platinum from the layer back to the negative contact would begin and would continue until the system was returned to equilibrium.

If B were taken less than A initially, transfer would not be toward the positive, but instead would begin at a low rate toward the negative. As the metal of the positive contact built up on the negative, the asymmetry would gradually disappear and the rate of transfer would increase to the value for like contacts of the metal of the positive contact.

Confirmation of the Analysis

The analysis indicates that continued transfer of contact material under these test conditions can be prevented by forming an "equilibrium layer" on the positive contact which equalizes A and B and thereby prevents further change. Confirmation of this conclusion was obtained from erosion tests whose results appear in Table III. The tests were performed under the standard conditions previously listed.

In Table III the height of the buildup has been used as a measure of transfer. Rows 1 to 5 show the transfer for like pairs of five contact materials. The natural bridge diameters for these materials were given in Table I; for platinum, palladium, and platinum +20 iridium they are large in comparison with those of silver and gold. Hence a combination of any one of these with silver or gold may be expected to exhibit strong asymmetry transfer.

Rows 6 to 10 illustrate the formation of an equilibrium layer on the positive contact when the metal of larger bridge diameter is negative. For platinum against gold, platinum against silver, and platinum + 20 iridium against gold the layer is very thin. For palladium against gold and palladium against silver, it is of measurable thickness. Also, when the metal of larger bridge diameter is positive, the buildup is somewhat larger than for like contacts of that metal. This is presumably due to the high initial rate of transfer indicated in Case I.

In row 11, with platinum +20 iridium negative and platinum positive, the asymmetry was insufficient to prevent transfer to the negative but merely reduced the initial rate. This corresponds to B less than A in Case II. Hence both arrangements of the contacts resulted in transfer to the negative, although at different initial rates.

In row 12, an equilibrium layer formed on palladium when platinum was negative. This was unexpected in view of the near equality of bridge diameters for these metals.

In row 13, transfer was to the negative in both cases. This was expected because of the lack of a great difference in bridge diameter between gold and silver. Also, the strong natural asymmetry of these metals in like pairs appears to be present in their combinations.

How effectively transfer is prevented once equilibrium has been reached is shown for platinum +20 iridium against gold, in row 14. Increasing the number of operations by a factor of 24 caused no further change, aside from a spreading of the area of erosion, when the platinum +20 iridium was negative. A huge buildup resulted in half this number of operations when the platinum +20 iridium was positive. Micrographs of the test contacts are shown in Figure 8.

With the exception of the platinum-palladium pair, the prediction of these results by the analysis was surprisingly accurate, especially since factors such as alloying, differences in melting and boiling points, and thermoelectric effects were not considered in the analysis.

In considering the molten bridge, a distinction must be made between the asymmetry to be expected of like contacts and that of a combination of two materials which differ considerably in natural bridge diameter. The former may be caused by Thompson or Peltier heating and has been assumed by some investigators[1,2,3] to be a cause of bridge erosion. The transfer caused by it is invariant for a given current, and should be classed with the A transfer forces for the purposes of this paper. On the other hand the artificial asymmetry of the combination has been shown to cause a high initial rate of transfer which is self-reducing.

When it was stated in the section on Transfer Tests, that asymmetric bridges in like pairs caused greater transfer than symmetric ones, it was tacitly assumed that the measured diameters were characteristic of the molten bridge alone. It was later found that even at the low inductance of this testing circuit electrical discharges may have occurred in the separating contacts, with resultant enlargement of the crater in the positive contact. Hence, the observed asymmetry which originally suggested the use of combinations may possibly, in certain cases, have been due to arcs, and the correlation of transfer results with asymmetry may have been partly coincidental. However, the finding which was suggested is a valid one, as shown by much experimental confirmation.

Scope and Applications

It has been shown that the formation of an asymmetric bridge by pairing electrical contacts which differ in natural bridge diameter creates a transfer process which is here called "asymmetry transfer" or B. This process is self-limiting and can nullify other transfer actions. It is self-limiting because the gaining electrode becomes similar to the losing electrode, thereby removing the driving force for the action. If no other action is present, asymmetry transfer will continue until both contacts become alike as far as the molten bridge is concerned. In the case of platinum against gold at five amperes, this occurs when the thickness of the layer of platinum on gold is on the order of 2 bridge diameters. If other transfer actions are present, the process will still be self-limiting if (1) B is greater than the resultant, A, of these actions and (2) is opposite to A in direction. Transfer will cease when B becomes equal to A. The thickness of the equilibrium layer will then depend on the relative magnitudes of B and A and will vary from about 2 bridge diameters when A equals zero, to zero when A equals B.

Thus, "self-limiting transfer" is said to exist when B is greater than A and the two are opposite in direction. Circuit conditions and practical arrangements of contacts for the attainment of self-limiting transfer will now be considered.

Transfer tests on platinum contacts at 6.3 volts and inductances up to 1×10^{-3} henry show that: (1) at currents below about 1 ampere short arcs cause negative transfer which increases with inductance, and (2) at larger currents increasing negative transfer occurs up to a critical inductance at which normal arcs begin. The normal arc causes positive transfer and is much more severe than the short arc. Each of these arc-transfers falls here into the A category.

It is of interest to examine the ranges of current and inductance for which the effects of arcs can be counteracted by the asymmetry transfer of a platinum-gold combination. These have been determined very approximately and are indi-

cated in Figure 9. The shaded area is the region of self-limiting transfer for the combination platinum (−) against gold (+) at 6.3 volts. The lower boundary is the locus of points at which short arc transfer and asymmetry transfer are equal and opposite. The upper boundary is the locus of points at which normal arcs begin. By reversing the combination, self-limiting transfer can be obtained a short distance beyond the upper boundary. Tests were made also at 50 volts and show that self-limiting transfer exists at least up to 1×10^{-8} henry at a current of one ampere.

An odd consequence of Figure 9 is that erosion of this combination, occurring under conditions below the lower boundary can be prevented by increasing the current.

The limits of Figure 9 are for the case of negligible capacity across the contacts ($\sim 10^{-11}$ farad). By placing a capacitor across the contacts the boundaries can be moved to considerably higher inductances. Also, the limits apply to contacts having opening velocities below certain maximum values, which have been determined by Lander and Germer[4] for one circuit of low inductance.

From known values of A for a pair of platinum contacts, it is possible to estimate the value of B for the platinum-gold combination. At 5.3 amperes, B is on the order of 5×10^{-11} cubic centimeter per operation.

For the present purpose contact materials may be classed as I or II depending on whether their relative natural bridge diameters are small or large, respectively. Any member of Class II may be used with any member of Class I to prevent the transfer of contact material under conditions of self-limiting transfer. Examples of materials which have been used successfully are gold, silver, copper, and molybdenum in Class I and platinum, palladium, platinum 80-iridium 20, palladium 60-silver 40, and gold 90-nickel 5 in Class II. While many other materials can be used for Class II, those for Class I may be limited in number. Small natural bridge diameters are favored by low electrical resistivity and not so many materials meet this requirement. Base metals can be used also, but if chosen as the Class II material an inert atmosphere may be necessary.

Figure 8. Erosion of the combination Pt–20Ir against Au at 5.3 amperes: (a) Pt–20Ir (+), Au (−), 1,000,000 operations, (b) Au (+) Pt–20Ir (−), 2,066,000 operations. Magnification—40x

Since self-limiting transfer requires that B be greater than A it is desirable to choose combinations of materials which enhance this difference. The following factors are determining:

1. Ratio of the natural bridge diameters of the Class II to Class I material. Available data indicate that B increases with this ratio. Relative melting and boiling points may also be pertinent.[4]

2. Current. The volume of the molten bridge, and hence B, increases rapidly with current.

3. The value of A for a like pair of the Class II material. As the bridge breaks, first B transfer occurs, depositing Class II material on the Class I contact. Then A transfer occurs, removing some of the deposited material. Hence of two different combinations having equal values of B, that having the lesser value of A for the Class II material will be more effective.

So far, self-limiting transfer has been

Figure 7 (left). Postulated bridge shapes and transfer vectors for the platinum-gold combination

Figure 9 (below). Region of self-limiting transfer for platinum (−), gold (+). Boundaries approximate

discussed in terms of a pair of dissimilar homogeneous contacts, one of Class I and the other of Class II. A more flexible arrangement, which is independent of polarity, utilizes duplex contacts. For example, by pairing two copper contacts each faced with a layer of platinum about two or more bridge diameters in thickness, self-limiting transfer can occur for either direction of A. Removal of platinum from either contact, decreases the bridge diameter in that contact and sets up an asymmetry which opposes the transfer. If the asymmetry is strong enough, self-limitation will occur.

It is interesting that a contact combination of a Class I base metal and a Class II noble metal can be used successfully under conditions which would rapidly oxidize the base metal. This is the case for platinum(−) against copper (+) at 6.3 volts, 5.3 amperes, and low inductance. Because of the equilibrium layer, contact is actually between two surfaces of platinum.

The formation of an equilibrium layer may be considered to advantage as a means of depositing a layer of Class II material on a Class I material. The layer is firmly bonded by fusion and is uniform in thickness, although rough on a microscopic scale.

The thickness can be varied from less than 2×10^{-4} centimeter to over 2×10^{-3} centimeter at 5.3 amperes by changing the inductance of the circuit and remains at a constant value once equilibrium has been reached. This technique would be useful for small areas not conveniently accessible by other means. For example, a disk or marking of platinum could be deposited on a flat sheet or curved surface of gold or copper.

Summary

Careful examination of contacts operated under conditions in which bridge erosion predominates shows that, despite a gross transfer of material from anode to cathode, the explosion of a molten bridge leaves a small crater in each contact. The diameters of such craters are believed to be those of the molten bridge just before rupture and they vary with current and with resistivity of the contact material in the expected manner.

Although for some materials the bridge has equal diameters in the two contacts, in other cases it is asymmetric, that is, the diameters in the two contacts may differ considerably. Results of bridge erosion tests suggest that a transfer of material in the direction of the smaller end of the bridge is associated with such asymmetry.

By pairing two materials which differ in natural bridge diameter, an artificial asymmetry is created. The transfer tendency of such a combination is called here asymmetry transfer and is shown to be self-limiting, because the act of transfer causes the gaining electrode to become similar to the losing electrode, thereby removing the driving force which causes the action.

The concept of self-limiting transfer is developed, whereby it is shown that a condition of zero net transfer will result if contacts are operated under conditions so that, (a) asymmetry transfer is greater than the resultant of other transfer forces acting on the contacts, and (b) is opposite in direction to that resultant. Because of the large values which asymmetry transfer has for certain combinations, the transfer of contact material can be prevented not only under conditions in which bridge erosion predominates but also, to some extent, in the presence of arcs.

Contact materials may be classed as I or II depending on whether their natural bridge diameters are small or large, respectively. Any member of Class I may be used with any member of Class II to establish a condition of self-limiting transfer. Instead of two homogeneous contacts, one of each class, it is equally effective to use two similar duplex contacts, each having a thin Class II layer on a Class I base. Such a configuration is independent of polarity or change in polarity and may be used to conserve precious metals.

Since a thin, Class II layer whose thickness is invariant with time is formed on the Class I base at equilibrium, the principles described here suggest a means of coating one metal on another in a well-bonded layer of uniform but controllable thickness.

The Magnetic Properties of Stainless Steels

WILLIAM A. STEIN
ASSOCIATE AIEE

Synopsis: This paper presents the results of an extensive investigation of the magnetic properties of solid stainless steel specimens. The analysis includes direct and alternating current magnetization curves, hysteresis loops, eddy current losses, and hysteresis losses. These tests were performed over a temperature range of −70 degrees to 600 degrees Fahrenheit. A discussion of the difficulties that might be encountered using stainless steel in magnetic circuits is included.

STEELS containing varying amounts of nickel and chromium have been found to be resistant to chemical corrosion and oxidation, and for this reason are grouped under the general name of stainless steel. Little thought was given to their adaptability in electromagnetic circuits, as it was a generally accepted fact that most of the nickel-chromium steels were nonmagnetic or relatively poor in magnetic characteristics as compared with silicon steel. However, the manufacturers of solenoid valves encountered so many valve failures in attempting to use regular steel in valves exposed to acid vapors, that they were forced to resort to the magnetically inferior stainless steels. As this is a highly specialized use of stainless steels, it was not surprising that none of the steel companies had available data on their magnetic properties.

In order to avoid excessive fabrication cost, the valve manufacturers had been using solid stainless steel sections instead of laminated pieces. This meant a large percentage of the over-all heat losses in the valve under alternating current conditions would be due to eddy currents. Without any data indicating the magnitude of this eddy current loss, the valve designers had no way of knowing whether the reduction of losses by laminating would offset the additional cost. This meant that the test specimens for this investigation had to be of about the same cross sectional size as the finished valve piece; approximately a one-half inch square.

Testing Difficulties

Testing solid specimens with alternating current in itself presented a unique problem in equipment design and laboratory procedure. It was impossible to find much information in any previously published literature concerning this technique, since most a-c tests are run on laminated specimens. This is due to the fact that data obtained on a specimen of a certain cross sectional area using alternating currents would not be applicable, except in a qualitative sense, to a specimen of the same material but of different area. This limitation is attributable to the fact that the magnetic flux does not completely penetrate the specimen, and eddy currents are of such proportions that they distort the magnetic properties of the steel.

Since stainless steel has poor magnetic characteristics, it was essential that the testing apparatus should be capable of producing unusually high magnetomotive forces. Another important requirement was that the apparatus should be built to withstand temperatures of 600 degrees Fahrenheit.

Since solid specimens were used, it meant that the ends of the bars could not be butt lapped as with laminated specimens. In order to reduce the air gap between the bars, the ends were polished and clamped together by auxiliary pieces of soft steel.

The Stainless Steel Specimens

Six different types of the more common stainless steels were obtained for this research from the Carpenter Steel Company of Reading, Pa. A special analysis of the chemical content of each, and an accurate record of all heat treatments was made. The important data on these six specimens of Carpenter stainless steel is shown in Tables I and II.

D-C Tests

D-c normal magnetization and permeability curves, Figure 1, were obtained for the six specimens up to 1,500 ampere-turns per inch. The first portion of the curve from 10 to about 300 ampere-turns per inch was obtained by a modified Epstein tester; the upper portion of the curve was obtained by a special permeameter. It was possible to check these curves up to 700 ampere-turns per inch by means of a General Electric permeameter[1] type *LC*, form *C*. This permeameter had been adopted by the Bureau of Standards and the American Society for Testing Materials as a standard method of test. The results of the General Electric permeameter agreed with those of the modified Epstein tester and special permeameter within 2 or 3 per cent.

Both the modified Epstein tester and the special permeameter were made of heat resisting materials. The coils were wound with glass insulated wire on mykroy forms, impregnated with Dow Corning 993. The supporting frames were of brass mounted on an asbestos base. With this special equipment it was possible to vary the temperature from −70 to 600 degrees Fahrenheit.

Paper 48-275, recommended by the AIEE basic sciences committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted May 27, 1948; made available for printing September 20, 1948.

WILLIAM A. STEIN is with the department of electrical engineering, Washington University, St. Louis, Mo.

The material for this paper was extracted from an industrial research report performed for the Alco Valve Company, St. Louis, Mo. by D. A. Fischer and William A. Stein, both with Washington University.

Figure 1. D-C normal magnetization and permeability curves for all six specimens tested at room temperature

$$\text{Permeability} = \frac{0.313 \text{ kilolines per square inch}}{\text{ampere turns per inch}}$$

In Figure 2, the d-c normal magnetization and permeability curves for specimen *A* are shown for various temperatures. The data at −70 degrees Fahrenheit coincided so closely with that at room temperature, that it was omitted from the figure.

The hysteresis loops of three of the specimens are shown in Figure 3. The residual magnetism of the steels are high; hence, special care must be taken that the valves do not stick magnetically. It is also quite evident that the hysteresis losses of stainless steel parts are quite large compared to ordinary steels.

A-C Tests

The a-c magnetization curves were, in most cases, plotted to about 500 maximum ampere turns per inch. In some cases, however, it was found that the sample being tested, heated too fast due to core losses at high flux densities to take accurate readings. For this reason, some of the curves in Figure 4 were not carried to 500 maximum ampere turns per inch.

In order to measure the maximum ampere turns per inch, it was necessary to obtain the peak current. The current to be measured was sent through a standard resistance, and a maximum reading vacuum tube voltmeter connected across the standard resistance indicated the maximum *IR* drop.

Figure 2. D-C normal magnetization and permeability curves for specimen A tested at room temperature, 400, and 600 degrees Fahrenheit

$$\text{Permeability} = \frac{0.313 \text{ kilolines per square inch}}{\text{ampere turns per inch}}$$

It will be noted that the vertical ordinate is plotted as maximum flux density in lines per square inch. This was calculated from the formula:

$$B_M = \frac{E_{AV} \times 10^4}{4NfA}$$

E_{AV} was the average voltage read across the search coil by a vacuum tube voltmeter. It has been proved by Camilli[2] and others that the maximum flux density is proportional to the average voltage regardless of the wave shape of the voltage, provided the wave did not cross the zero line more than once per cycle.

The total core losses per pound at varying temperatures and at frequencies of 25 and 60 cycles were determined for all six specimens. These core losses were run

Figure 4. 60-cycle a-c normal magnetization curves for all six specimens tested at room temperature

Figure 6. Eddy current and hysteresis losses per pound of specimen A tested at room temperature and 600 degrees Fahrenheit, and at 25 and 60 cycles

on a sine wave basis. If the form factor differed from 1.11 by more than 2 per cent, a correction was applied.[3] Figure 5 shows the total core losses in watts per pound at 60 cycles tested at ambient temperature.

The core losses for each specimen were divided into their component parts and plotted against maximum flux density. Such a curve is shown in Figure 6 for specimen number *A*. It is quite apparent that the eddy current losses at 60 cycles are intolerable. At 25 cycles the eddy current losses are of the same relative magnitude as the hysteresis losses. These curves clearly show the effect of temperature on both hysteresis and eddy current losses.

According to Steinmetz[4,5] alternating flux does not completely penetrate a solid specimen due to the screening effect of the eddy currents. The magnetic flux in the interior of the steel specimen is not in phase with the flux at the surface, but lags behind it. The magnetic flux at the surface is caused by the impressed magnetomotive force, whereas the flux in the interior is due to the resultant of the impressed magnetomotive force and the magnetomotive force of the eddy currents. Progressing from the surface toward the interior, the magnetic flux gradually lags more and more in phase and at the same time decreases in intensity. In the case of a thick bar or a high frequency alternating magnetomotive force, the center might be entirely free of flux lines.

Rosenberg[6] and other investigators[7] developed formulae for separating the hysteresis and eddy current losses in solid specimens. In Rosenberg's analysis the eddy current losses varied as the specific resistivity to the one-half power and as the magnetomotive force to the two-thirds power. Unsuccessful attempts were made to use these formulae with the data of this experiment.

In these tests it was only possible to determine the average value of the maximum flux densities in the bar, as the flux density was obtained by dividing the average electromotive force of the search coil wrapped around the specimen by $4\ ANf\times10^{-8}$. It was found that the plotting of $(P_h+P_e)/f$ versus f for a particular average value of the maximum flux densities produced a straight line graph. This meant that the hysteresis losses varied directly as the frequency and the eddy current losses varied directly as the frequency squared. The losses were then separated by the usual method of holding the average value of the maximum flux densities in the specimen constant and varying the frequency.[8] Special care was taken not to vary the frequency over too wide a range, as flux distribution is a function of frequency. Precautions were also taken to prevent the core losses from heating the specimen. Readings had to be made quickly and a cooling off period was allowed between successive readings. Figure 6 shows the hysteresis loss as staying essentially constant from about 67 to 75 kilolines per inch. This discrepancy indicates that the separation was not too accurate in the higher ranges of flux densities; however, the results do show the relative magnitudes of the individual losses.

Figure 5. Total core losses per pound for all six specimens tested at 60 cycles and at room temperature

Effect of Nickel Content in Nickel-Chromium Steels

In order to determine the effect of nickel on the magnetic properties of steel, similar tests were conducted on some nickel-chromium steels. Among those tested were an Allegheny Ludlum type *414* which contained 12 per cent chromium and 2.5 per cent nickel and an Allegheny Ludlum type *431* which contained 16 per cent chromium and 2.5 per cent nickel. The curves from these tests are not shown in this report. However, it was found that these steels compared favorably with the Carpenter steels previously examined.

Attempts were made to run tests on nickel-chromium steels containing 8, 10, 12, and 20 per cent nickel. However, it was impossible to detect any magnetism with the testing equipment.

Conclusions

From the results of these tests and similar experiments, it is to be concluded

that the smaller the amount of chromium present, the more magnetic the stainless steel will be. Those steels with the low chromium content of about 12 or 13 per cent also had a much higher residual magnetism. An examination of Figure 5 will show that the low chromium stainless steels, specimens *A* and *E*, had a lower core loss per pound than the other types. Steels can tolerate up to 2 or 3 per cent nickel without serious detrimental effects on their magnetic characteristics. Steels having in excess of 8 per cent nickel are nonmagnetic; and can be used for valve parts subjected to corrosion and oxidation, but which are not included in the magnetic circuit.

As seen from the hysteresis loops, the product of the residual magnetism and the coercive force is considerable, and hence stainless steels make fair permanent magnets. In order to overcome this permanent magnetism it was necessary to insert a small spring in the solenoid valve opposing the electromagnetic action.

When the energizing current is shut off, the spring overcomes the residual magnetism and snaps the plunger back into its normal position.

After examining the eddy current losses of the solid specimens, such as in Figure 6 which shows the losses per pound of specimen *A*, it becomes apparent that a laminated plunger although more expensive is quite necessary. Otherwise, the eddy current losses in the plunger would be so great, that heat would be radiated into the solenoid coil of the valve and cause an excessive temperature rise.

Proximity Effect Factors for 3-Phase Coaxial Busses Comprised of Square Tubular Conductors

THOMAS JAMES HIGGINS
MEMBER AIEE

HENRY P. MESSINGER
NONMEMBER AIEE

THE THEORY underlying design of 3-phase coaxial busses comprised of square tubular conductors, Figure 1, has been developed by us in a recent paper.[1] In section VIII of this paper:

"It is determined that the proximity effect factors of a given bus of coaxial square tubular conductors are essentially equal to the corresponding factors of a "similar" bus comprised of circular tubular conductors, Figure 2, each of which has external diameter and thickness respectively equal to the external side and thickness of the corresponding square conductor.

"It is pointed out that in consequence of this equality the proximity effect factors can be calculated through use of Dwight's[2] curves (Figure 3 is a partial reproduction of these curves) for the ratios R_{ac}/R_{dc} of the conductors of a 3-phase coaxial bus comprised of circular conductors."

This calculation is to be effected as follows. Corresponding to a given bus comprised of square conductors, effect the "similar" bus of circular conductors. From well-known theory, a circular tubular conductor carrying a current, of which the density can vary radially but not angularly over the cross section, produces no flux within the tube. Accordingly, the metal of the inner conductor of a coaxial bus comprised of circular tubular conductors lies in a field produced only by the conductor itself. Thus the proximity effect factor K_p of the inner conductor is one; whence the ratio $R_{ac}/R_{dc}=K_sK_p$ of the inner conductor is equal to the skin effect factor K_s.

In turn, as skin effect factor depends only on self geometry, the appropriate curve of Figure 3 for the inner conductor also yields the skin effect factor of the intermediate conductor. Then if the value of R_{ac}/R_{dc} for the intermediate conductor is divided by this skin effect factor, the proximity effect factor of the intermediate conductor is obtained. Obviously, the proximity effect factor of the outer conductor is to be obtained in the same fashion. But, inasmuch as the proximity effect factors of the given bus and of the corresponding "similar" bus are the same, it follows that the desired proximity effect factors of the given bus have been obtained.

In illustration of this calculation consider the following example: to calculate the proximity effect factor for an intermediate square conductor having standard dimensions[3] of edge $c=10$ inches and thickness $t=(c-d)/2=0.5$ inch. From Figure 3 the skin effect factor for the "similar" circular conductor of ratio $t/D=0.5/10=0.05$ is $K_s=1.25$ (taken from the 0.05 curve for inner tube); the ratio R_{ac}/R_{dc} is 1.285 (taken from the 0.05 curve for outer tube). Hence, the proximity effect factor is $K_p=1.285/1.25=1.028$.

To obviate need of calculation and to render better accuracy the curves of Figure 4 have been plotted from points with co-ordinates calculated as in the first example. From these curves can be obtained by inspection the proximity effect factors of the intermediate and outer conductors (that of the inner conductor is 1) of a 3-phase coaxial bus comprised of square tubular conductors. Illustratively, the 0.05 curve for outer conductor yields the value $K_s=1.03$ for the conductor of the first example.

To determine the co-ordinates of Figure 4, a photograph of the original cut (Figure 2 of reference 2) of Dwight's curve was enlarged about three times. From this enlargment, and aided by the fact that the curves were plotted on a grid of fine mesh, the co-ordinates of points on the curves could be obtained with considerable accuracy. From these values were calculated the co-ordinates of the curves of Figure 4. The two sets of co-ordinates are contained in Tables I

and II. They enable the interested designer to plot to a larger scale and on a finer grid the curves of Figure 4. As regards Figure 3, the original curves (Figure 2 of reference 2) extend to smaller values of t, are plotted on a grid with mesh one-fifth the size of that of Figure 3, and render values sufficiently accurate for engineering purposes (the values of K_s in example 1 were taken from the original curves).

It is to be mentioned that the curves of Figures 3 and 4 are for 60-cycle balanced currents with relative phase angles $\theta = 0$ degrees, $\theta = 120$ degrees, and $\theta = 240$ degrees. However, essentially the same values are associated with opposite phase sequence; again values of K_s and K_p corresponding to any other frequency are to be obtained by multiplying the actual conductor thickness by $(f/60)^{1/2}$ and then using the curves as above.

Stabilized Permanent Magnets

P. P. CIOFFI
MEMBER AIEE

PERMANENT magnets are stabilized against forces tending to demagnetize them, by partial demagnetization. It is shown that after such stabilization, the magnet operates at a point on a secondary demagnetization curve. This curve may be treated identically as the major demagnetization curve is treated in ordinary magnet design problems. Formulas are developed for determining secondary demagnetization curves from the major demagnetization curve when stabilization is achieved by magnetization of the magnet before assembly, and by an applied magnetomotive force after magnetization in assembly.

Since the development of permanent magnet alloys with improved characteristics, rapid advances have been made in the application of permanent magnets. Alloys of the Alnico type, characterized by high coercive force and energy-product, have made it possible to generate high stable fields in air-gaps of large volume more economically than with electromagnets. The degree of utilization of the energy furnished by the permanent magnet is dependent, however, upon the particular application. In applications where the magnet is not subjected to significant demagnetizing forces, such as in magnetic circuits for loudspeakers, light valves, and magnetrons, the magnet can be designed to operate at its maximum energy point on the demagnetization curve. However, in applications where the magnet is subjected to partial demagnetization because of applied demagnetizing forces, the necessity for magnetization before assembly or because of operation in a circuit of variable reluctance, the magnet operates at a point within the demagnetization curve quadrant, and the magnet delivers less energy to the air-gap. Examples of such applications are receivers, generators, and polarized relays. Under this condition of operation, a degree of stabilization is obtained which makes it necessary to use a larger magnet volume than would otherwise be needed. The problem of optimum design of stabilized permanent magnets has been studied by several investigators.[1,2,3]

It will be shown that when the magnet is partially demagnetized for the purpose of stabilization, its operating point lies on a curve which, for convenience, will be called a secondary demagnetization curve. The object of this paper is to discuss the derivation of secondary demagnetization curves for given conditions of stability against demagnetizing forces and their applications to magnet design problems.

Discussion of the Magnetization Cycle

Let us assume that the magnet is magnetized while asssembled in its magnetic circuit and then partially demagnetized for the purpose of stabilization. The magnetic cycle is illustrated in Figure 1. When the magnetizing force H_s for saturating the magnet to B_s is removed, the magnetization drops to the point P on the demagnetization curve. This point is determined by the intersection of the load or air-gap line OP with the demagnetization curve. An applied demagnetizing force H_d diminishes the magnetization to the point Q, determined by the intersection of the line QH_d drawn from H_d parallel to the air-gap line OP. Upon removing the demagnetizing force H_d the magnetization proceeds along the lower branch of a minor hysteresis loop to Q' on the air-gap line. Upon reapplication of the demagnetizing force H_d, the magnetization diminishes along the upper branch of the minor loop back to Q. The slope of the line connecting the tips of the minor loop QQ', is a measure of the reversible permeability of the material, which for all practical purposes may be considered constant for loops originating on the demagnetization curve.[4] The magnetization represented by the point Q' is stable to any temporarily applied demagnetizing force not exceeding H_d because the minor loops are reversible. It is evident from Figure 1 that for a given state of magnetization Q' the demagnetizing force for cyclic conditions may be determined from a simple graphical construction.

If the magnet is stabilized by magnetization out of assembly, its magnetization may be represented by M, Figure 2, given by the intersection of the out-of-assembly air-gap line OM with the demagnetization curve. Upon assembly in the magnetic circuit, the magnetization proceeds to M', the intersection of the minor loop with the closed circuit air-gap line. H_d in this case is the maximum demagnetizing force for which the magnet is stable. Its graphical determination is given by the intercept on the H axis of the line MH_d drawn from M parallel to the air-gap line OP.

The two methods described for stabilizing the magnet are fundamentally similar. In the first case, partial demagnetization is obtained by an applied demagnetizing force, while in the second case, partial demagnetization is obtained by the self-demagnetizing force under open circuit conditions.

Under either condition, the operating point of the magnet (B and H co-ordinates) after stabilization is fixed by the terminus of the tip of the minor loop on the closed circuit air-gap line OP. The location of this point is dependent upon the reversible permeability, the degree of demagnetization and upon the slope of the air-gap line OP. The locus of this point, as the air-gap line slope changes from zero to infinity, is a curve passing through H_c and B_r, which will be called a secondary demagnetization curve. This curve may

Paper 48-277, recommended by the AIEE basic sciences committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted August 4, 1948; made available for printing September 8, 1948.

P. P. Cioffi is with the Bell Telephone Laboratories Inc., Murray Hill, N. J.

be treated identically as the major demagnetization curve in the magnet design problem. Since the secondary curve lies below the major demagnetization curve, the magnet, under stabilized conditions, will operate at a lower energy level. Thus, the problem is to derive the secondary demagnetization curve from the major curve for given conditions of stability.

The Secondary Demagnetization Curve

A. Stabilization by Magnetization before Assembly

Referring to Figure 2, let M represent the open circuit magnetization having the co-ordinates B_1, H_1, and M' the closed circuit magnetization with co-ordinates B_2, H_2 after assembly in the circuit. OP and OM are respectively the in- and the out-of-assembly air-gap lines. The slope of OM is

$$S_1 = \frac{B_1}{H_1} = \frac{\varphi_1}{A}\frac{l}{H_1 l} = \frac{l}{AR_1} \tag{1}$$

where l is the magnet length, A its sectional area and R_1 is the open circuit reluctance of the air-gap. Similarly

$$S_2 = \frac{B_2}{H_2} = \frac{l}{AR_2} \tag{2}$$

where R_2 is the closed circuit reluctance of the air-gap of the assembly.

From equations 1 and 2 the relationship between S_2 and S_1 is obtained:

$$S_2 = kS_1 \tag{3}$$

where $k = R_1/R_2$. R_1 and R_2 are determined from a magnetic circuit analysis.

The secondary demagnetization curve may now be derived graphically from the major demagnetization curve. Figure 3 shows the major demagnetization curve B_r, P, M, H_c and its corresponding energy-product curve B_r, A, O for the permanent magnet material, Remalloy. Assume a line of slope S_1, and from equation 3 the corresponding line of slope S_2. For this illustration $k = 7.5$. From the intersection M of the air-gap line of slope S_1 with the major demagnetization curve, the line MN is drawn with slope equal to the reversible permeability μ_r. Its intersection with the air-gap line of slope S_2 gives a point M' on the secondary demagnetization curve. Other points are obtained for various assumed slopes S_1, and the curve passing through these points is the secondary demagnetization curve B_r, M', H_c. Its corresponding energy-product curve is the curve B_r, C, D, O. These curves are a function of k alone and families of curves are obtained for various values of this parameter.

The secondary demagnetization curve may also be obtained directly and with higher accuracy by the analytical determination of successive points on this curve as follows:

From Figure 2,

$$\frac{B_2 - B_1}{H_1 - H_2} = \mu_r \tag{4}$$

The simultaneous solution of equations 1, 2, 3, and 4 gives

$$H_2 = \frac{H_1(\mu_r H_1 + B_1)}{\mu_r H_1 + kB_1} \tag{5}$$

and from equation 4

$$B_2 = \mu_r(H_1 - H_2) + B_1 \tag{6}$$

By taking successive values of B_1 and H_1 on the major demagnetization curve, corresponding values of B_2 and H_2 are determined and the secondary demagnetization curve and the energy-product curve may be drawn.

The method of magnetizing the magnet out-of-assembly yields after assembly a degree of stability against demagnetizing magnetomotive forces which may be computed for any point on the secondary demagnetization curve.

Figure 2. Stabilization by magnetization before assembly

Referring to Figure 2

$$S_2 = \frac{B_1}{H_1 - H_d} \tag{7}$$

the solution of equations 1, 3, and 7 gives

$$H_d = \frac{H_1(k-1)}{k} \tag{8}$$

and the corresponding magnetomotive force to which the magnet is stable is

$$F_d = H_d l \tag{9}$$

where l is the length of the magnet.

For a given stabilizing magnetomotive force, F_d, the point on the secondary demagnetization curve derived before for which the magnet assembly is just stable can be determined as follows. If B_2, H_2 are the co-ordinates of this point, the magnet magnetomotive force is

Figure 3. Secondary demagnetization curve and corresponding energy-product curve of Remalloy for stabilization by magnetization before assembly

Figure 1. Stabilization by magnetization after assembly

Figure 4. Stabilization by demagnetization with a given magnetomotive force

$$F = H_d l \tag{10}$$

then

$$\frac{F_d}{F} = \frac{H_d}{H_2} \tag{11}$$

and we will let

$$\frac{F_d}{F} = c \tag{12}$$

that is, the ratio c of the demagnetizing field to the operating field is fixed. From a solution of the preceding equations we find

$$S_2 = \frac{\mu_r[k(c-1)+1]}{k-c-1} \tag{13}$$

Figure 5. Secondary demagnetization and energy-product curves of various materials for constant stability

and the intersection of the air-gap line of slope S_2 with the secondary demagnetization curve previously derived gives the desired operating point of the magnet. The range of the degree of stabilization, c, obtainable is from $\frac{k-1}{k}$ to $k-1$ as S_2 goes from zero to infinity.

B. Stabilization by Demagnetization with a Given Magnetomotive Force After Magnetization in Assembly

In this method of stabilization, the magnet is magnetized after assembly and then stabilized by applying a reverse magnetomotive force, F_d, equal to the maximum magnetomotive force for which the magnet is expected to be stable. The problem is to derive a secondary demagnetization curve for which all points on this curve will provide the same amount of stability. This curve is in general of a different shape from the variable stability curve derived in the preceding section.

Referring to Figure 4, if Q', with coordinates B_2, H_2 represents a point on the secondary demagnetization curve B_r, Q', H_c, being discussed, equations 9, 10, 11, and 12 apply for every point on the curve,

$$F_d = H_d l$$

$$F = H_2 l$$

$$\frac{F_d}{F} = \frac{H_d}{H_2} = c$$

and the secondary demagnetization curve will correspond to a fixed value of the parameter c.

In the graphical solution, the point Q' is uniquely determined by the slope of the parallel lines OP and H_dQ, the reversible permeability μ_r and the ratio c of H_d/H_2. This point may be found by trial on an assumed air-gap line and the curve passing through a series of points determined for various air-gap lines is the required curve.

The secondary demagnetization curve may be obtained directly and with greater accuracy by the analytical determination of successive points on this curve.

Referring to Figure 4,

$$\frac{B_2 - B_1}{H_1 - H_2} = \mu_r \tag{14}$$

$$S_2 = \frac{B_2}{H_2} \tag{15}$$

$$S_2 = \frac{B_1}{H_1 - H_d} \tag{16}$$

The simultaneous solution of equation 11, 12, 14, 15, and 16 gives

$$H_2 = \frac{(B_1 + \mu_r H_1)\left[(c+1) - \sqrt{(c+1)^2 - \frac{4\mu_r c H_1}{B_1 + \mu_r H_1}}\right]}{2\mu_r c} \tag{17}$$

and

$$B_2 = \mu_r(H_1 - H_2) + B_1 \tag{18}$$

directly from equation 14.

By assuming values of B_1 and H_1 on the major curve points on the secondary demagnetization curve corresponding to a given ratio c of F_d/F may be obtained. This curve also goes through B_r and H_c.

Optimum Magnet Dimensions from Secondary Demagnetization Curves

The magnet length, l, in centimeters and area, A, in square centimeters are given by

$$l = \frac{F}{H_2} \tag{19}$$

and

$$A = \frac{F}{RB_2} \tag{20}$$

where R is the reluctance and H_2 and B_2 are the co-ordinates of the operating point on the secondary demagnetization curve. The magnet volume is given by

$$V = lA = \frac{F^2}{RH_2B_2} \tag{21}$$

which is a minimum when H_2 B_2, the energy-product of the operating point, is a maximum. For case (B), therefore, the magnet of minimum size and weight is determined by the proportions corresponding to the maximum energy-product on

Figure 6. Curves for obtaining optimum magnet dimensions for various degrees of stability

the secondary demagnetization curve.

For case (*A*) under the heading, The Secondary Demagnetization Curve, the minimum magnet dimensions are similarly determined by the maximum energy point on the secondary demagnetization curve. However, if these proportions do not provide sufficient stability, as indicated by equations 11 and 12, it will be necessary to operate at a point on the secondary demagnetization curve given by its intersection with the air-gap line as determined by equation 13. In general when there is a choice between the stabilizing methods of sections (*A*) and (*B*), (*B*) will give the smaller magnet.

Secondary Demagnetization Curves for Several Materials

The secondary demagnetization curves and corresponding energy-product curves, calculated by method (*B*) for several permanent magnet materials for various ratios c of demagnetizing field H_d to the operating field H_2 are illustrated in Figure 5. The curves show that with increasing degree of stabilization, because $(B_2H_2)_{max}$ occurs at slowly increasing values of B_2 and rapidly diminishing values of H_2, the optimum magnet becomes longer and slimmer. The reciprocals of H_2 and (B_2H_2) at maximum energy-product, proportional respectively to the optimum length and volume of the magnet, are plotted as a function of c in Figure 6 and illustrate the rapid increase in optimum magnet dimensions required with increasing degree of stabilization. These curves may be used with equations 19 and 21 for the solution of any problem requiring optimum magnet dimensions over a wide range of stabilization.

Television Receiving Systems

C. M. SINNETT
NONMEMBER AIEE

THE GROWTH of television during the past year has exceeded the most optimistic postwar predictions. Many factors have contributed, but probably the most important ones were the televising of such events as the Worlds Series baseball games, the Army-Navy football game, the heavyweight fights, and the political conventions which created a public desire for receivers and the development, design, and manufacture of large quantities of popular-priced receiving instruments to satisfy this desire. Thus television has turned the corner and bids fair to become an industry surpassing the automobile industry. Most of the immediate problems have been solved, but new ones are constantly appearing which will test the mettle of the engineering fraternity before complete solutions are found.

Antenna Considerations

Television signals, by virtue of their location in the frequency spectrum, are normally limited to line of sight transmission. Under unusual atmospheric conditions, however, such signals may be received at locations hundreds of miles from the transmitter. At present the first five television channels are located between 50 and 88 megacycles and the remaining seven channels between 174 and 216 megacycles. Each television channel is 6 megacycles wide with the picture and sound radio-frequency (r-f) carriers separated by 4.5 megacycles. Amplitude modulation with one side-band suppressed is employed for picture transmission. Frequency modulation to a maximum deviation of ±25 kilocycles is used for sound. The effective radiated power from television transmitters, for antenna heights greater than 500 feet, is so regulated as to give the same coverage as would be obtained with 50 kw at 500 feet. Thus, if the antenna height is only slightly greater than 500 feet, the effective radiated power can be nearly 50 kw, but must be decreased as the antenna height is increased.

The foregoing information indicates broadly some of the factors which must be considered in the design of a television receiving antenna such as, broad frequency band coverage, controllable directivity, good signal pickup, ease of installation, and low cost. No single antenna, available at present, fully meets all of these requirements. Fortunately, however, with the majority of television transmitting antennas located near the center of a city, it is possible to provide satisfactory reception with comparatively simple receiving antenna structures. These are the half-wave dipole or the half-wave dipole plus reflector used as all channel antennas. Special requirements may dictate the use of a half-wave folded dipole and reflector for the lower frequency channels and a smaller folded dipole and reflector for the higher frequency channels. Under some conditions the foregoing combinations may be necessary to provide satisfactory signal pickup in outlying areas. The dipole and reflector has been found to meet the requirements in a high percentage of the installations to date.

Figure 1 shows the response characteristics of dipoles and reflectors cut for various resonant frequencies. In each case the reflector is spaced approximately 0.2 wave length from the antenna with the antenna directed toward the transmitter. It will be noted that an assembly resonant to the lower frequencies will provide essentially the same signal pickup at the higher frequencies as can be obtained from similar assemblies cut for the latter frequencies. The converse is not true, however, and consequently such antenna systems are tuned to the low frequency television channel. The reflector contributes about 50 per cent additional signal pickup to that obtained from a simple dipole. Folded dipoles while giving greater signal pickup at the resonant frequency tend to be more selective and are used only when local conditions dictate the need for greater signal pickup, then can be obtained from dipole-reflector assemblies. A single folded dipole and reflector assembly providing the increased pickup will serve for the higher television channels, since the total frequency band coverage required of the antenna represents only 20–25 per cent of the carrier frequency employed.

A directivity pattern of a receiving antenna assumes importance when its location is such that reflected signals or man-made static are problems. A high front-to-back ratio, obtained by stacked arrays, may be required under certain circumstances. This is the exception rather than the rule, however, as indicated by the almost universal use of the dipole and reflector assembly.

Figure 2 shows the polar characteristics of the dipole and reflector at 44 mega-

Figure 2. Polar characteristic of dipole and reflector at 44 megacycles

Figure 3. Polar characteristic of dipole and reflector at 174 megacycles

cycles. A front-to-back ratio of nearly two-to-one is obtained with null areas along the axis of the dipole.

Figure 3 shows the polar characteristics of the same antenna assembly at 174 megacycles. The two lobe pattern of Figure 1 has become a sort of four leaf clover pattern with lobes existing at approximately 38 degrees from those at the lower frequencies. Essentially the same pattern is obtained at 216 megacycles. In many instances, this change in pattern between the two television bands works to the advantage of the viewer since a compromise orientation can be made between low and high frequency stations providing optimum performance on both. In other instances two antenna assemblies, together with adequate phasing or switching means, may be necessary.

An antenna which will pick up the signal is only part of the story. On the average the antenna is located some 70 feet from the receiver and requires some form of transmission line between the two. Prior to World War II a transmission line representing the best compromise between cost and performance had losses of the order of 5 decibels per hundred feet at 50 megacycles and 12 decibels per hundred feet at 200 megacycles. Under some conditions, this meant that an increase in antenna elevation could be nullified by the losses of the transmission line extension. During the war a new dielectric, known as polyethylene,[1,2,3,4] was developed for use at ultra-high-frequencies. This dielectric, while expensive, had excellent electrical and mechanical properties. A parallel wire transmission line, using polyethylene as a supporting medium, was developed for use with television antennas and receivers. This line has a characteristic impedance of approximately 300 ohms, is relatively low priced and has extremely low losses. Figure 4 shows these latter characteristics over the

Figure 4. Loss characteristics of RCA bright picture television transmission line

range 20 to 200 megacycles. Even at the highest television frequency, 216 megacycles, the loss is less than 2 decibels per hundred feet. Many other uses have been found for this line such as matching stubs, folded dipole antennas, and impedance transformers.

The Television Signal

The composite television signal contains all the information necessary to synchronize and produce a picture at the receiver. It contains horizontal and vertical synchronizing signals, return beam blanking, and video or picture information including tonal gradations from black to white. The horizontal pulse rate is 15,750 cycles per second and the vertical pulse rate is 60 cycles per second.

Figure 5 shows this composite signal for several horizontal lines and two vertical fields. The television picture employs interlaced scanning 525 lines, 60 fields, 30 frames per second. Observation of the figure indicates the relative heights of synchronizing, blanking, black level, video modulation to white level and zero carrier. This signal, after detection in the receiver, is separated and fed to the video amplifier and the horizontal and vertical synchronizing circuits.

Figure 6. Block diagram of a conventional television receiver

Direct Viewing Receiver

Figure 6 is a block diagram of a conventional television receiver indicating the various functions. The r-f signals, video and sound, picked up by the antenna are fed to the r-f unit. This unit, which can be tuned by suitable means to any one of the 12 television channels, converts the various high-frequency video and sound r-f signals to fixed intermediate frequencies (i-f) of 21.25 megacycles for sound and 25.75 megacycles for video. At the output of the r-f unit these two intermediate frequencies, including the necessary side bands, are fed to the sound and video intermediate frequency amplifiers. The sound channel provides the necessary i-f gain to properly operate conventional frequency modulation (f-m) detector circuits. Audio amplification follows and is fed to a dynamic type loudspeaker. The video r-f amplifier consists, in this case, of stagger-tuned stages to provide the necessary amplification and band width and feeds a conventional amplitude detector. From the detector the video signal is applied to a video amplifier consisting of two stages. This amplifier is a-c coupled and introduces an a-c axis about which the video signal tends to swing unless some form of correction is applied.

This correction takes the form of a

Figure 5. Television synchronizing waveform for amplitude modulation

Figure 7. Cut-away view of an optical barrel in the Schmidt optical system

Figure 8. Arrangement of optical system for a home television receiver employing reflective optical principles

This design gives a large-screen picture with a console cabinet no deeper than that of an ordinary home radio receiver

d-c restorer which corrects the picture tube grid bias to suit the various scenes. In addition the d-c restorer circuit provides partially separated synchronizing signals which are applied to the input of the synchronizing signal chain. Here, synchronizing is separated completely from picture and in turn directed to the vertical pulse and sawtooth generator and to the horizontal sawtooth generator and "fly-wheel" circuit. The vertical sawtooth is applied to the vertical deflection coils comprising one portion of the deflection yoke surrounding the neck of the picture tube. The fly-wheel circuit in addition to providing a pulse for proper operation of the horizontal discharge tube, insures complete horizontal synchronization of the picture under practically all conditions met in the field. The horizontal discharge or output tube provides the necessary deflection current to the horizontal windings of the deflection yoke and in addition, through a step-up transformer provides approximately 9,000 volts, after rectification, to the picture tube. A conventional low voltage power supply completes the receiver.

For all its apparent complexity a television receiver is comparatively easy to operate. Seven major controls are provided on the front panel comprising station selection, fine tuning for sound, horizontal synchronizing, vertical synchronizing, picture contrast, picture background, and an audio volume control. As the art progresses it may become feasible to eliminate front panel controls of horizontal and vertical synchronizing, fine tuning and picture contrast. At the present time several other screw driver adjustments are provided on the chassis for horizontal size, vertical size, horizontal and vertical centering, linearity, and focus. When properly adjusted at the time the receiver is installed readjustment is seldom required.

Projection Receivers

While the mass market for television receivers will probably involve the lower-priced table models, there is a relatively large demand for pictures of larger size than can be produced economically by means of direct viewing picture tubes. To meet this demand, various projection systems have been proposed. Two of these have assumed some prominence; the refractive or conventional lens system and the reflective or Schmidt system. Neither of these fully satisfies the requirements. The refractive system, while more flexible in adapting picture size to varying viewing conditions and requiring less cabinet space, is not as efficient as the Schmidt system. Since light output is expensive to obtain in a television receiver, the trend has been toward the more efficient Schmidt system.

Figure 9. The Schmidt optical system using a reflective screen

Figure 10. The Schmidt optical system using a 42-inch spherical mirror and a 12- or 15-inch picture tube

Figure 7 shows a cut-away view of an optical barrel such as is used in the Schmidt optical system. Normally, a four- or five-inch diameter picture tube, operating at 27,000 volts second anode, is used. The surface of the face of the picture tube has a curvature which is designed to work properly with the spherical mirror and aspherical lens of the reflective optical system. The tube faces the mirror which is located in the bottom of the optical barrel. Reflected light rays from the spherical mirror pass through an aspherical lens and are brought to sharp focus on the viewing screen. By proper design it is possible to construct such an optical system with a magnification of six, a "throw" of roughly 36 inches and obtain resolution of over 1,500 lines in the corners of the picture. The effective aperture of such a system is of the order of f 0.8.

For use in the home, it is desirable that

the viewing screen, used for television projection, possess certain optical characteristics. A picture will seldom, if ever, be viewed from the extreme sides because of image distortion; consequently, the screen is provided with directional characteristics which conserve the available light and result in a gain in light output over that obtained with the ordinary diffusing screen. Experience has indicated that such a screen, possessing a horizontal included angle of roughly 60 degrees and a vertical included angle of 15–20 degrees, will meet practically all the requirements. In a transmissive screen the horizontal and vertical directivities are obtained by means of vertical ribs on the front surface of the screen and a Fresnel lens on the back, the screen having been moulded from clear plastic with a diffusing interlayer. In a reflective screen a metal reflector is provided with microscopic vertical lines plus a light spray of diffusing material to obtain horizontal directivity and is then slightly curved about a horizontal axis to provide the desired vertical directivity. With either screen a gain in light output of the order of five to seven times that of the ordinary diffusing screen is obtained. Both systems are in current use and provide a picture of adequate brightness and resolution having dimensions of 20 inches by 15 inches.

Figure 8 shows the general layout of the Schmidt system using a transmissive screen.

Figure 9 shows the same type optical system employing a reflective screen.

The Schmidt optical system has been employed for theatre television projection on a screen 24 feet by 18 feet. Figure 10 shows such a system using a spherical mirror 42 inches in diameter and a picture tube which may be either 12 or 15 inches in diameter. This constitutes the largest Schmidt-type optical projection system in use in the world today.

In conclusion it should be stated that the foregoing discussion of television receivers is of necessity very brief. Many items of interest and importance have been omitted for the sake of brevity. It is sufficient to say that television is undergoing rapid changes which will eventually result in lower priced receivers having clearer pictures and greater contrast. With all that is being learned about black and white television and the application of this knowledge, plus the expenditure of large amounts of time and money to color television, its eventual introduction is assured. One should not be impatient, however, since color television will introduce many new and difficult problems which must be solved in the laboratory and substantiated by field tests before consideration can be given to it as a service to the public.

The Characteristics and Application of Precision, Snap-Acting Switches

A. L. RICHE
MEMBER AIEE

FROM the beginning of the use of electric power, switches have been required for its control, but until recently attention has been given to reducing their size, weight, and operating energy requirement, except for the work done with mercury contacts. Growth of the use of automatic controls, where mechanical motion is required to open and close electric circuits, has brought demand for units of greater refinement than those typified by the ordinary toggle switch and for freedom from the limitations of tilting mercury tubes.

The first of the family of devices now known as precision, snap-acting switches, made its appearance in 1927, and by 1932, variations of the original device gained commercial acceptance as the contacting elements in thermostats which controlled one-half horsepower oil burner motors, at line voltage, without the use of intermediate relays.

The reliable performance of these switches in thermostats led engineers to try them for other purposes, and it was soon recognized that here was a new tool of versatile usefulness. Growth in the variety and extent of its application has been so rapid that engineers and designers are not completely informed on many phases of the usefulness and the limitations of this newcomer among electrical controls.

The purpose of this paper is to outline the characteristics and the points which must be considered in the use of precision, snap-acting switches.

Dimensions, Operating Principle, and Characteristics

The dimensions and operating principle of the switch which was introduced in 1932 are indicated in Figure 1, and the characteristics of a typical unit, as now manufactured, are listed below.

1. Small size ($1^1/_4$ cubic inches).
2. Light weight (0.8 ounce).
3. Life of millions of operations when used on small loads.
4. Precise repeatability of operation at a given point in mechanical motion of the actuating plunger, maintained for many thousands of operations.
5. Operability by small force (10 ounces).
6. Operability by small motion (0.001 inch).
7. Resistance to the effect of vibration.
8. Capacity to control loads of 20 amperes, at potentials up to 460 volts alternating current.
9. Operability with substantial uniformity when tipped into different attitudes (as distinguished from the performance of mercury switches).

The basic operating principles shown in Figure 1 are used in many variations in size of unit and in operating means, which have been built to meet particular needs. Figure 2 illustrates a few examples.

There are now several manufacturers offering units which fall into the class of precision, snap-acting switches, some of which are interchangeable in size with those shown in Figure 2. A variety of operating principles differing from those shown in Figure 1 are used, but all employ noble metal, butt contacts driven by blade-type snap-acting mechanisms. Spring members usually are made from heat-treated beryllium copper. Most types are self-returning, but maintained contact varieties are available.

In addition to the variations in size, modes of actuation, and operating mechanisms, the characteristics of each type of switch are varied to meet the needs of particular applications. The terminology which has been developed for convenience in describing these characteristics is shown in Figure 3.

Selecting the Switch Best Suited to Each Job

The need for care in selecting switches for each application arises from the great variety of styles and operating characteristics which have been produced to meet the range of use-requirements. Two examples will illustrate the breadth of the range.

Among the 300 switches used in the 200-inch Mount Palomar telescope,[1] some operate only in emergencies but must repeat operation within 0.0002 inch of the

Figure 1. Basic switch operating mechanism

The long spring member is mounted in cantilever. Two shorter members rest in V's, which are positioned to bow them in compression. The contact, mounted on the free end of the spring, is held against an upper, fixed contact by the couple action of tension and compression forces. When plunger motion deflects the tension member downward, reversal of couple snaps the contact downward. Upon removal of operating force, cantilever action restores the system to its initial position, with snap motion

same point of actuating motion, regardless of changes in ambient temperature or lapse of time between operations. On the telescope, switches are not subject to vibration or impact and the maximum electric load on any switch is a 1/50th horsepower motor. Contrasted with this are switches of the same general appearance, but having different characteristics, which are used on giant punch presses and in rail sanding devices on railroad locomotives. In both of these uses impact and vibration are severe, reliability over many thousands of operations is the prime requirement, and in some cases heavy electric loads must be controlled, but the highest degree of repeatability is not needed.

Repeatability

The gauging operations and control of machine tool motion, shown in Figure 4, illustrate the use of switches where repeatability must be within ±0.0001 inch in 100,000 successive operations, and must not be measurably affected by normal changes in ambient temperature. When repeatability of this order is required, the operating plunger is carried in a close-fitting guide, and other precautions are taken to insure uniformly maintained point of application of operating force to the snap-acting spring.

Where high repeatability is required, electrical loading of contacts must be no greater than 10 watts at 120 volts alternating current or 5 watts at 25 volts direct current. The reason for this is seen in Figure 5, as even moderate electrical loading of contacts causes sticking which must be overcome by operating motion greater than that required to cause mechanical switch actuation at no load.

Operating Force

The total force required to operate a switch varies from 3 to 28 ounces, depending on the thickness of spring material selected for a given design, and with contact separation. Total operating force is often of less interest than differential force which, as shown in Figure 3, is the difference between total operating force and release force.

Small Differential Force

Switches operable by differential force as low as $1^1/_2$ ounces are used in sensitive thermostats of the type shown in Figure 6, in which partially-filled wafers or bellows are used as the temperature-sensitive element. Such elements provide ample motion, but the available differential force is small. Figure 7 illustrates the use of a force-sensitive switch for counting drops of dew as they are deposited on the end of a long lever arm.

Small Differential Motion

The expansion and contraction of metals or solid-filled bellows, such as are frequently used as the temperature sensitive element in thermostats, provide ample force, but the motion available for contact operation is extremely small. Switches designed for use in such instruments operate with a differential motion of no more than 0.0002 inch. This same type of switch is used to detect the deformation of machine parts beyond predetermined limits.

Switch Sensitivity Is not Synonomous with Precise Repeatability

Repeatability refers to the precision with which a switch operates in relation to a given point in the motion of the operat-

Figure 3. Definitions of special terms

Differential force = operating force minus release force

Repeatability is stated in terms of decimal fractions of an inch and refers to the maximum variation from a fixed point at which motion of the actuator of a switch causes it to snap over. It is usually specified with reference to a particular number of switch operations, such as 100,000

ing plunger, and has no relation to the differential motion, differential force, or the product of the two (which is differential energy) required to actuate that switch. Misunderstanding on this point has often led to the specification of switches having unnecessarily close differentials and consequently lower electrical capacity or shorter contact life than can be secured from switches of wider differential characteristics. Precision of repeatability is accomplished by construction which maintains a fixed point of application of operating force to the snap-acting switch blade.

Performance of Sensitive Switches on Large and Small Loads

Switches operable on small loads by mechanical energy on the order of 0.0008 ounce-inch are capable of opening and closing circuit on loads of several amperes at potentials up to 460 volts alternating current, but on such loads operating energy is increased by widening of both differential force and motion, as shown by Figure 5.

Special contact problems arise when such sensitive switches are used to control loads on the order of milliamperes or millivolts, for not only is initial pressure between contacts limited, but in all switches of this type contact pressure approaches and passes through zero at the instant of snapover. Experience shows that smooth, clean contact surfaces of the purest silver will not close circuit reliably on milliwatt loads. Good performance on such loads is accomplished by use of a serrated contact surface mating with a smooth-surfaced contact. One form of such serration is shown in Figure 1. This is further discussed under Contact Materials and Conformation.

Resistance to Acceleration, Impact, and Vibration

High pressure between contacts is necessary, not only for high electrical capacity but to resist the tendency of motion of the entire assembly to jar them apart or into false contact position. Contact pressure can be increased by the use of stiff spring elements, but it also bears the relation to contact separation as seen in Table I in terms of resistance to acceleration.

Switch Life

Switch life, referred to in Table I as probable mechanical life, represents the medium value of the number of operations performed before failure, as determined by a large number of tests.

On small electric loads, life is limited by the mechanical life of the snap-acting mechanism. On heavy electric loads, switch life is limited by disintegration of the contact material or the roughening of contact surfaces to the point where there is danger of sticking due to mechanical interlocking of the roughened surfaces. As indicated in Table I, mechanical life varies directly with contact spacings as a result of the necessary spring flexure. Contact life varies so widely with the type of switch and nature of the electric load that no comprehensive tabulation can be set down here. In many instances, however, probable life of 1,000,000 operations or more will be experienced when switches are loaded to their rated capacity.

Switching Capacity and Underwriters' Laboratories Rating

Precision, snap-acting switches are listed by Underwriters' Laboratories under the Special Use Snap Switch Standard.[2] Test procedures and listings under this standard provide only ampere, voltage, and sometimes horsepower ratings. These data are obviously insufficient for use by designers in determining the safety of switches on many applications, for they are silent as to the effect of power factor and the inrush current which must be handled on solenoid loads. Horsepower ratings are almost meaningless because of the irregular nature of motor characteristics.

Table I

Switch Type	Contact Separation, Inches, Nominal	Resists Acceleration, Stated in G*, Up to	Probable Mechanical Life, Operations
Highly sensitive	0.008	35 to 45	45,000,000
General purpose	0.020	75 to 80	20,000,000
Special wide contact separation	0.070	150 to 200	500,000

* G equals 32 feet per second per second.

A special section of the National Electrical Manufacturer's Association (NEMA) is now writing a standard which is intended to make ratings of precision, snap-acting switches meaningful and a reliable guide to their safe application. It must be remembered, however, that such a standard is a guide only to maximum safe loadings and that there are many uses for precision, snap-acting switches where heavy loading is not compatible with precision of repeatability nor with maximum contact life. On points of this kind, NEMA standards and Underwriters' listings are of little value, but switch manufacturers have accumulated much data which are gradually being organized and published. This is, however, a relatively new field and there are still many questions which can be answered only by special tests.

Paralleling preparation of an NEMA standard, Underwriters' Laboratories has undertaken special tests to determine the safety of certain switches under conditions of operation not covered by any standard and will apply the results of such tests in judging other applications. One such series of tests has been applied to a plastic-enclosed switch, of the size shown in Figure 1 but of different construction,

Figure 4. In and out motion of the cutting head on a machine tool is controlled by the switches shown at A

Pieces are gauged to close tolerance by the switches shown at B. Work above-tolerance in thickness stops downward ram motion before either switch is operated. Actuation of one switch only indicates within-tolerance and a dimension below-tolerance causes operation of both switches. An automatic version of this device is used for sorting optical blanks into three categories

Figure 5. Force and movement differential characteristics

Figure 6. Sensitive thermostat with safety alarm

The wafer operates directly against the main switch but if heat is not cut off by the regular switch, continued expansion moves the lever to operate a safety switch which both takes over control and closes the alarm circuit

to determine the suitability of the following rating.

Inductive Load
- Inrush 75 amperes, 460 volts, alternating current
- Steady State 20 amperes, 460 volts, alternating current

Heater Load 20 amperes, 460 volts, alternating current

Motor Load 3/4 horsepower 120 volts alternating current, $1^1/_2$ horsepower 240 volts, alternating current

Lamp Load 10 amperes, 125 volts, alternating current

Maximum permissible continuous ambient temperature 250 degrees Fahrenheit

A rating of this type is based on the experience that interruption of an a-c load of any kind is not the limiting factor, for within the voltage rating there is never any difficulty with extinguishing the arc. For example, on tests to establish the above rating, full inrush current of 75 amperes at 460 volts and at 35 per cent power factor was repeatedly interrupted with no arc persistence. This is distinguished from the effect of such loading on contact life.

Underwriters' Snap Switch Standard specifies a temperature rise of 30 degrees centrigrade above normal ambient as the rating limitation. This has been shown to be unnecessarily low when silver contacts are used[3] and spring elements are of beryllium copper or other material which retains its characteristics at high temperature.

The permissible continuous ambient temperature rating shown previously is determined by checking switch performance over 100,000 operations, under full electric load, during a 90-day period, while exposed to the rated ambient temperature.

The factors limiting switch ratings are: welding together of contacts on heater loads, and contact life on inductive loads. The reason for this limitation on heater load rating is that, unless special precaution is taken to prevent it, contacts come together with a bouncing motion, and the resulting arc melts contact materials which cause a certain degree of welding together of contact surfaces. On a heater load full current flows in the arc from the very beginning of the first bounce, whereas on inductive loads, such as motors or solenoids, full current does not build up until after the period of bounce is passed. The time during which high inrush persists on such loads is so short that inrush current many times the value of permissible steady state current can be handled satisfactorily. The same is true of a tungsten lamp load, for a lamp which draws 10 amperes after equilibrium is reached permits an instantaneous inrush on the order of 125 amperes when the filament is cold.

Contact Materials and Conformation

Fine silver contacts satisfactorily serve most purposes. However, smooth silver contacts, even though perfectly clean, cannot be depended upon for reliable closure of circuits on either a-c or d-c loads of the order of millivolts or milliamperes. Satisfactory performance has, however, been accomplished in switching thermocouple circuits and on minute a-c loads in aircraft circuits, by use of a fine silver serrated contact working against a smooth silver surface. Such a surface is shown in Figure 1. This success is attributed to increased unit pressure, as compared with that existing between smooth contact surfaces, the establishment of multiple contact points, and reduction of the probability of minute specks of foreign material holding contact surfaces separated. It is also probable that the knife-like edges of serrations cut through surface film on the smooth mating surface as the two come together with wiping motion. Tests of the performance of this contact arrangement have included introduction of fine dust of insulating material which causes immediate failure of smooth contact surfaces. Exposure to humidity and an atmosphere of sulphur dioxide has shown marked improvement in performance of serrated contacts, as compared with smooth-surfaced contacts. The good showing of the serrated surfaces under these tests is supported by many years of satisfactory field service under conditions where smooth contacts had given a great deal of trouble previously.

Figure 7. Drops of dew fall onto switch actuating arm and are recorded on electric counter

Since it is desirable to use one form of contact for the widest practical range of applications, field and laboratory testing has been undertaken to determine the suitability of the serrated contact for use

Protection for D.C. Heater and Incandescent Lamp Loads

751 to 1000	3	$\frac{1}{2}$	2	2

Figure 8. Contact protection on d-c loads

Figure 9. Special contact protection for large d-c heater loads

Figure 10. Special contact protection for large d-c inductive loads

on heavy, as well as extremely small, loads. The results of these tests have shown serrated contacts to be generally useful.

Contact Materials Other Than Silver

Pure silver is not the ideal contact material when electrical loading is such as to produce splash, which so contaminates insulating surfaces as to invite flashover. On d-c loads silver tends to transfer from one contact to the mating surface in the form of a peak and crater, and on all loads above a few watts there is some degree of sticking. All of these deficiencies stem from the low melting point of silver, and most attempts to remedy them are directed at so alloying silver as to retain its desirable features of high electrical and thermal conductivity and resistance to the formation of nonconducting surface film, and at the same time raise its melting point. Among the many proprietary silver alloys available, those containing copper, nickel, iron, and cadmium oxide have been found most useful in precision, snap-acting switches. There is not yet enough experience to justify general recommendations, but there is reason to believe that improved contact performance on some specified loads can be accomplished by selection of a contact alloy suitable to each.

Use on D-C Loads

This type of switch was designed primarily for use on alternating current, but d-c applications constantly arise. Millions of such switches have been used on 30-volt d-c aircraft applications on loads up to 25 amperes. Most switches for such use have contact separation of 0.070 inch, which separation is necessary to insure circuit interruption without sustained arcing, particularly at high altitudes. In general, no special arc-snuffing circuits are used on such low-voltage installations. On heavier aircraft loads, particularly where the frequency of operation is high, a special form of switch is used in which the arc is blown out by a permanent magnet.

Noninductive Loads

On d-c heater loads up to 60 watts at 115 and 230 volts, no contact protection is required. The circuit and values of capacitors and resistors to be used above that loading are shown in Figure 8. Use of this circuit not only insures snuffing of the arc but minimizes the transfer of contact material, which is always a serious problem on d-c loads. On loads above seven amperes at 230 volts, the circuit shown in Figure 9 is often effective. It has the particular advantage of being noncritical.

Inductive Loads

The switching of d-c loads, where even a moderate amount of inductance is present, introduces problems, many of which can be solved only by cut and try testing. There is no means for accurate, advance calculations of the performance of such circuits, and the usual procedure is to try various combinations of capacitors and resistors, connected in the circuit shown in Figure 8, and observe the character of the arc formed between switch contacts. Experience develops ability to judge when the best combination has been found, but in many instances extensive tests are necessary to supplement that judgment. In many instances the circuit shown in Figure 10 is found more useful than others, particularly on loads above those set out in the table of Figure 8. The values of capacity and resistance, shown in Figure 10, have been successfully used on the load there indicated, but, as mentioned in connection with the circuit shown in Figure 9, these values are not critical as are those shown in Figure 8 and may be used on loads varying materially from those indicated. The theory of the operation of this circuit is not well understood, but experience has shown it to be effective as an arc suppressor. It does not, however, inhibit the transfer of contact material as well as the simple combination of capacity and resistor connected across the switch contacts.

Double Pole, Double Throw Switches

Most precision, snap-acting switches are of the single pole variety. There has, however, been an ever-increasing demand for double pole construction, particularly for use on aircraft and by the Signal Corps. The types developed during the war have not been entirely acceptable because of their size and weight. This is shown full scale in Figure 11, together with a new unit which is interchangeable in size with the commonly-used single pole switch. See Figure 1 for dimensions. This new unit provides for simultaneous action of both poles in each direction, with sustained positive pressure between contacts up to the instant of their

Figure 11. Double-pole double-throw switches

The smaller switch is physically interchangeable with switches of the size shown in Figure 1

Figure 12 (above). Contact pressure characteristics

Figure 13 (below). Bracket overtravel actuators

separation. This is accomplished by simultaneous application of hammerblow action to both current-carrying members by a separate snap-acting mechanism.

Pressure Between Contacts

Figure 12 illustrates the change in pressure between contacts as the operating plunger moves through the operating differential. This shows that as the snap point is approached contact pressure approaches and passes through zero. When the speed of operating motion is greater than about 0.001 inch per minute, this type of operation has proved to be entirely satisfactory for the great majority of uses, particularly when the switch is not subject to vibration. Difficulty may be experienced, however, under certain conditions, where the mechanical drive is extremely slow or where the operating plunger of the switch normally is held near the operating point most of the time, as in thermostats. The difficulty is exaggerated if the switch is so mounted as to be vibrated synchronously with the power supply, as, for example, by the vibration of a motor or by air pulses from a fan. In such an assembly the switch is moved bodily in one direction on one half of the cycle and in the other direction on the second half. Inertia of the moving contact tends to hold it stationary which results in the switch acting as a rectifier. Under such conditions the contacts rapidly deteriorate due to arcing on the half-wave rectified current. When it is not practical to avoid such synchronous vibration, switch contacts can be so mounted as to sustain positive contact pressure up to the instant of separation.

Auxiliary Actuators and Housings

For many uses the mechanical motion available for operating switches is either so wide or so lacking in uniformity as to make its direct application to precision, snap-acting mechanisms impractical. Overtravel devices must necessarily be introduced to absorb the excess or variable operating motion. Some of the mechanisms available as parts of basic switches are shown in Figure 2. Others are made portions of special brackets, or of the metallic housings which are required for protection of basic switches against mechanical damage, oil, coolant, water, or corrosive or explosive atmospheres, Figures 13 and 14.

Future Development of Switches

The field of usefulness of this general type of switch will expand with ever-growing use of automatic and semiautomatic mechanization of manufacturing, merchandising, the control of temperature, humidity, and such functions as the lowering and raising of windows. These will be met by refinements and adaptations of present switches, with the probability that there will become available completely sealed, compact, lightweight units free from all environmental effects and filled with an inert gas under such pressure as will adapt it to direct as well as alternating current use, in a manner not attainable with present designs.

Discussion

L. M. Perkins (Allen-Bradley Company, Milwaukee, Wis.): The development of precision snap-acting switches in the multitude of forms and the accuracy of performance in which they are now available is an impor-

tant contribution to industry. I am sure we all appreciate having had the opportunity of reading Riche's clear and interesting discussion of the many and varied applications to which these switches are adapted, and he and his associates are to be congratulated for their important contributions.

Riche has discussed one of the more common types of switches and has described the wide field in which it can be expected to give excellent performance. He has also brought it to our attention that there is a limited field in which the same excellent results cannot be expected with this construction of switch. This limited field includes temperature controls, pressure switches or mechanical motions where the rate of change is so slow that the switch may be held in one position near the snap-over point for an appreciable time.

Of the other types of precision snap-acting switches available, some give their best performance in the same field as the switch discussed in the paper. Others are available for use in those particular applications having slow application of operating force where th switches discussed do not give their best performance. These different types are similar in having the contact mounted at the end of a flexible spring but they differ in the form of the toggle spring used to produce snap over and also in the place where the operating force is applied.

As you know, the switches described by the author consist basically of a contact mounted near the free end of a flexible member with the two integral edge strips so bent down and so pivoted as to give the effect of a compression toggle spring pivoted at a point below the axis of the flexible member. This construction holds the moving contact against a stationary contact mounted above the axis. The operating force is applied to the central portion of the flexible member near its fixed end. As this force is increased, it acts to decrease the contact force both because of the beam action of the flexible member and because the line of action of the tensile force in the flexible member is brought closer to the stationary pivot of the toggle. When the contact force reaches and passes through zero the contact will snap across from the upper to the lower stationary contact. It is possible by change in construction details to increase or decrease the force between contacts immediately after snap over but the contact force must always pass through zero before snap over can occur. The smaller the force between contacts after snap over the less will be both force and travel differentials but also the less will be the current handling capacity of the switch.

In another of the more common types of these switches, the contact is likewise mounted at the free end of a flexible member but the toggle spring is pivoted at the end of a second spring instead of on a rigid point. The operating force is applied to this second cantilever spring near its fixed end, instead of directly to the contact spring as in the principal type discussed in the paper. This second type can be so proportioned as to fit the same applications as the type first discussed, in which case the contact force will go through zero before snap over just as in the first type. However, it is also possible to so modify this second construction that the contact force will not drop to zero except at the instant of snap over when the moving contact is leaving one stationary contact to

Figure 1

Figure 2

travel over to the other stationary contact.

To obtain this result it is necessary to add resilience between the operating force and the end of the second cantilever spring where the toggle spring is pivoted. This may either be a spring, interposed between the operating force and the cantilever spring, or the cantilever spring itself may be made more flexible between the point where the operating force is applied and the end where the toggle is pivoted. For correct operation this resilience must very closely balance the toggle action, with the toggle a little stronger than enough to reach this balanced condition.

This construction gives the results shown in Figure 2 of the discussion where increase in operating movement causes the contact force to decrease to a certain point and then to suddenly pass through zero to a higher value against the other stationary contact. One important feature of this construction is that the switch cannot be so operated as to hold a condition of almost zero contact force where slight vibration would cause arcing at the contacts. Another feature is that the change in force at the contact on snap over is so large that incipient welds are broken loose without any effect on the normal differential of the switch such as is shown in Figure 5 of the paper. A third feature is that the higher contact force after snap over increases the ability of the switch to close on and carry larger currents under conditions of slow change in operating force combined with vibration.

So this modified type, including resilience between the operating point and the toggle, is a switch which can be used with excellent results on those applications where the switches may not give satisfactory performance. It is obvious that this increase in contact force before snap over can only be obtained at the expense of greater differential in both force and travel.

Royce E. Johnson (Barber-Colman Company, Rockford, Ill.): Riche has included a large amount of useful information in his paper, for which I wish to compliment him. I am certain that had it not been for the pioneering work by the author and his associates in developing the precision snap-acting switch, the state of the art would be much less satisfactory than it now is. Lack of such switches would have greatly handicapped our industrial, military, and aircraft control development in World War II.

It is interesting to translate Riche's figures for switch operating power and contact performance into the concept of power amplification. The curves in Figure 5 indicate that a differential force of about 2 ounces and maximum movement of 0.0008 inch will handle a 1,100-watt resistive load. Assuming that this net input of 0.0016 inch-ounces takes place in 0.1 second, the power represented is 0.00013 watts. The ratio of 1,100 to 0.00013, or 8,500,000, then represents the power amplification of this device if computed for a 0.1 second time interval. For a 1-second interval the ratio would be ten times greater. The development of pulse techniques for use in electromechanical servo systems may provide another application for this switch which is, in effect a power amplifier.

The travel time of the armature in opening one contact and closing the other in a type *BZ* switch is between 5 and 6 milliseconds, a period which is appreciably shorter than the operating time for ordinary relays. This too is a desirable characteristic in servo controls.

Results of life tests which we have run, using alternating current, are in agreement with Riche's statement that a heater load is more difficult to handle than the same current for an inductive load. Oscillograms show that there may be as many as three bounces when the contacts close, which subjects the contacts to several opening and closing operations at a rate of between 1,000 and 2,000 times per second. The full current is handled at each operation, as the author states, when the load is noninductive.

This bouncing of the contacts leads to the subject of antibounce contacts. Would it not be possible to mount the moving contact on a secondary slightly preloaded spring, or to cushion mount the stationary contacts so as to absorb the energy which causes contact bounce? Such construction might be warranted for certain applications requiring long life or freedom from bounce for other reasons, one of which is radio noise.

An arc suppression circuit which we have found even more effective than the one shown in Figure 10 for a 10-ampere 110-volt resistive or inductive load uses a 2-microfarad capacitor and about 1/4-ohm resistance connected across the contacts as in Figure 8, but includes in addition a small half-wave selenium rectifier in parallel with the load. The polarity of the rectifier is such as to prevent passage of current when the switch is closed. This virtually short circuits the inductive transient voltage of the load when the contacts open. A rectifier rated at only 0.1-ampere 110-volts continuous duty lasts quite well where contact operations occur 500 times per minute. This arc suppression circuit, which we use (with different constants) for sensitive polarized relays, keeps the switch cool whereas it gets quite warm within a few minutes if the circuit of Figure 10 is used. Oscilloscopic observation shows that the rectifier circuit prevents contact arcing while for Figure 10 the

arcing persists until a few milliseconds after the opposite contact has been made.

A. L. Riche: Perkins' discussion expands matter referred to only indirectly in the paper, and on which I am glad to comment.

Perhaps his most important point, contained in his last paragraph, is that switch characteristics required to meet conditions of severe vibration, combined with slow rate of actuation, can only be obtained at the expense of differential operating energy greater than that required for satisfactory operation under the less severe conditions of the great majority of switch uses. This observation applies to several methods for meeting severe requirements, which will be discussed.

Perkins has dealt with one means for producing switch characteristics to meet special operating conditions. It is introduction of resilience between operating force and the toggle device, either inherently in the switch mechanism or externally.

The usefulness of such resilience to meet special conditions has long been recognized, and is most commonly provided by a leaf spring mounted on the cover of the basic switch, as shown in Figure 3 of the discussion. This construction not only provides resilient actuation, but more frequently is used as a compact, low cost means for securing overtravel of actuating motion and protection of the switch against excessive actuating force. Such leaf springs, or equivalent coil springs, are combined with switch construction details to provide the desired pressure between contact immediately after snap-over, as described by Perkins.

The claims made for a form of mechanism which may embody inherent actuating resilience, is that with such construction snap motion begins before pressure between contacts falls to zero. This is theoretically true, but is not unique to the mechanism described, for the same result occurs when any of several other forms of snap-acting mechanisms are actuated by means suitably balanced in resilience with the respective toggle mechanisms. This is true because of the drooping characteristic of the curve of operating motion versus operating force.

In any such case the amount of sustained contact pressure, which can practicably be accomplished by the critical balance Perkins discusses, is so small as to lack significance. The beneficial effect which does result from the use of resilience is probably due to continuous contact motion, once separation has begun. This reduces chattering, due to vibration, and causes clean break on slow actuation.

Successful use of switches without introduction of actuating resilience, in the great majority of their many uses, is probably due to the effect of minute welds which are broken only when positive contacts separating force exists. The effect of such welds on switch operating differential, as shown in Figure 5 of the paper, is often less objectionable than the increased operating energy differential requirement which results from introduction of resilience, either external or inherent in the switch structure.

For these reasons, I believe that there is no magic in any particular snap spring of this general type, but that the choice of mechanism is dictated by the ease and practicability of adjusting it to provide the operating characteristics desired for any given use. This point is of considerable importance, as it is probable that the wide and varied use of this type of switch is largely due to the ready availability of switch characteristics which fit closely each particular job.

It is possible that the advantage of providing resilience inherently in the spring, instead of providing it externally only when required, may somewhat limit the versatility of the inherently resilient construction. In particular, the unavoidable higher differential operating energy requirement sets a limit to its use in thermostats or pressure-responsive devices, where the smallest possible operating differential is the requirement. A switch of the construction described cannot be used where only extremely small operating motion is available.

Immunity to the effect of vibration is required only under special conditions, such as mentioned in the paper as occurring where switches are used in thermostats which are exposed to vibration produced by motors or motor-driven fans, supplied from the same power source as that controlled by the switch. In such operation the switch is near the point of snap-over most of the time, and when the switch is moved in one direction on one half-wave and in the opposite direction on the second half-wave, contacts may separate on one phase and close on the other to produce a rectifying action which seriously injures contacts. In most cases this difficulty can be overcome by reorienting the switch mounting relative to the direction of vibration. A more general solution is to mount the moving switch contact on an auxiliary resilient member, as shown in Figure 4 of the discussion. This arrangement allows the moving contact to follow motion of the fixed contacts, when vibration exists, in such a manner as to avoid chattering and the rectifying action. This construction also maintains contact pressure up to the instant snap motion begins, but the full reason for its success in many installations where it serves well in the presence of severe vibration is no doubt quite complex for it involves the natural period of response of the entire system. Satisfactorily close, differential performance in thermostatic uses has been experienced with this type of contact mounting.

Figure 3. Energy stored in a resilient actuator accomplishes maintained contact pressure up to the point of snap at the expense of increased differential operating energy

Figure 4. Suitable resilient contact mount maintains contact pressure until snap begins, and resists the effect of vibration

Figure 5. Double snap construction offers the highest resistance to vibration and impact

There are applications where neither of the methods shown in Figures 3 or 4 of the discussion provide the necessary resistance to the effects of vibration or impact. A particular instance is that of a switch used in an air pressure control on aircraft. The switch is mounted directly on a compressor motor running 1,500 rpm, where the excursion of vibration is material. Ample operating energy is available in this instance, and the structure schematically shown in Figure 5 of the discussion performs satisfactorily. Here a mechanical snap mechanism drives a snap-acting switch of the type which remains in one or the other of the positions until driven to the opposite. Positive pressure between contacts exists until the hammer-blow action, provided by lost motion in the linkage, accomplishes rapid separation. In this type of switch, the effect of minute contact welds does not appear in operating force, movement, or differential changes.

This same type of mechanism is successfully used to produce simultaneous make and break in multipole switches such as are coming to be widely used on aircraft. One example of a compact switch of this type is illustrated in Figure 11 of the paper.

I appreciate Johnson's remarks and stimulating suggestions.

Contact bounce is a subject of great importance, for the study of which special equipment has been developed. At the present time it appears that a solution may lie in quite a different direction from the resilient mounting of fixed contacts. The encouraging results of tests now underway are not, however, mature enough to discuss.

Johnson's timely remarks on the usefulness of rectifiers for arc extinction on direct current, may be supplemented by reference to a paper by Dallas and McCully,[1] which deals with extension of contact life by arcless interruption of 50 milliampere loads at 120 volts direct current.

A question was asked from the floor regarding Underwriters' listing of switches of this general type, particularly as to such listing under Industrial Standards. Most such listings have been under the Special Use Snap Switch Standard,[2] which in reality does not at all fit precision, snap-acting switches, as they are distinctly different in both construction and the field of application from the manually operated toggle switches around which the standard was written. It is believed that a new standard may be provided at an early date under which this distinctly different type of switch will be listed by the Underwriters. In the meantime, at least two manufacturers list precision, snap-acting switches under the Industrial Standard covering switches for one horsepower and less rating.

Speed Governing Design Considerations for Multivalve Condensing Steam Turbine-Generators

J. W. BARNETT
NONMEMBER AIEE

THE PROBLEM of the proper approach to correct speed governing system design was little understood during the early days of central station turbine generators. As central station plants expanded, capacities and interconnection of distribution systems took place and the problem of governing became more complex to the designer and more critical to the central station systems. Early slow and cumbersome governing systems had to be replaced by more rapid and flexible systems. The trend from 1,800 rpm turbine generators to 3,600 rpm units of mounting pressures and temperatures has required that governing systems become increasingly rapid and more responsive to minute system frequency changes.

Turbine-generator manufacturers had tried previously to meet governing specifications as requested by the purchasers for their individual system requirements. No standard requirements had been set up to assist the purchaser in determining what governing requirements could readily be met by the turbine-generator manufacturers and should be required to be met by them for satisfactory governing. Such a concrete set of requirements had been attempted at intervals, but it was not until the joint committee of AIEE and ASME issued a Recommended Specifications for Speed Governing of Prime Movers Intended to Drive Electric Generators[1] that this need was fulfilled. These specifications have recently been further expanded and now cover all steam turbine-generators intended to drive units of 500 kw and above.

A speed governing system is described in this paper, consisting of a rotating pilot valve governor, a valve servo-motor of the skirted piston design, and cam-operated governor-controlled valves, and comprise one type of system which satisfactorily meets all requirements as specified in Recommended Specifications for Speed-Governing of Steam Turbines Intended to Drive Electric Generators Rated 500 Kw and Up.[2]

Governor-Controlled Valves

A speed governing system suitable for controlling a typical condensing turbine generator is shown in Figure 1. This mechanism consists of a symmetric set of upper and lower cam-operated governor-controlled valves of the poppet design with venturi seats. The valve disks have freedom of motion relative to their stems and are provided with a spherical surface to insure tight seating. The valves are operated in proper sequence by the cams to give a load curve of kilowatts versus valve servo-motor stroke which approaches a straight line. The camshaft is positioned by the valve servo-motor through a rugged mechanism using a rocker-arm sector and pinion arrangement.

Valve Servo-Motor

The valve servo-motor is positioned by a double-acting secondary pilot valve capable of admitting high pressure oil to the operating piston of the valve servo-motor. The valve servo-motor is so designed that rapid closing time is assured by providing a skirt on the power piston in order to decrease the piston area in the closing direction to about 50 per cent of the area provided in the opening direction. The power required in the closing direction is much less than that required in the opening direction, because the springs of the individual governor-controlled valves and unbalanced steam forces in the closing direction of the governor-controlled valve disks assist the closing of the valve servo-motor. For a given required closing time of the valve servo-motor, the skirted piston arrangement requires that the main hydraulic pump capacity be only one-half of that required for a valve servo-motor without the skirt. Eliminating the skirt materially increases the power requirements of the pump as well as its physical size. This would not be desirable in the large size units, since it would represent a considerably increased fixed loss to the purchaser.

A valve servo-motor with the skirted piston arrangement will require an opening time twice that of the closing time. This increased time of opening is quite satisfactory since it is not desirable to open the valve servo-motor at the same rate as required in the closing direction.

Speed Governor

The speed governor is the heart of the speed governing system and upon its sensitivity depends the turbine generator's ability to follow system frequency changes. The basic element of the speed governor is the rotating pilot valve. This pilot valve is positioned in a vertical plane by a speed-sensitive governor head driven from the main turbine shaft through a worm and worm wheel. High pressure oil from the main pump is

Paper 48-280, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted August 3, 1948; made available for printing September 20, 1948.

J. W. Barnett is with the steam turbine engineering division of the General Electric Company, Schenectady, N. Y.

Figure 1. Speed governing system for condensing steam turbine-generator

Figure 3. Speed governing system sensitivity

admitted through a load limiting pilot valve to the sliding bushing of the governor rotating pilot valve. The oil passes through the feed port of the bushing into the rotating pilot valve, and then to the single acting speed relay piston. Within the range of the governor setting, the rotating pilot valve possesses the ability to admit high pressure oil to the speed relay piston which accurately positions the speed control mechanism and admits steam through the governor-controlled valves.

Figure 2 shows a typical speed governor fully enclosed within the turbine front standard. The relation of the speed governor to the other component parts of the speed governing system is clearly shown.

Starting Handwheel and Load Limit

When the turbine-generator is at rest or coming up to speed, the governor head weights are against their inner stops and the rotating pilot valve is unable to position the speed relay piston because the feed ports in the sliding bushing will be wide open until the action of the weights in the governor head displaces the rotating pilot valve enough to throttle the oil at the bushing feed port. To take care of the starting condition, the starting handwheel which is mechanically linked to the load limiting pilot valve positions the speed relay piston. Once the rotating pilot valve takes control of the speed governor, the handwheel may be turned to its wide open position. The handwheel and auxiliary pilot valve may also perform a second important function. The mechanism may be used as a load limit under normal operating conditions and will limit the amount of speed relay piston travel in the opening direction to limit the load. This setting will not interfere with the rotating pilot valve's ability to unload the machine in response to high system frequency.

Speed Changer

At about 89 per cent speed the turbine-generator reaches the speed governor setting, and at this point the speed changer may be used to control the machine either manually at the turbine or motor-operated from the electrical control room. Two stops are provided on the speed changer. One provides an upper limit of governor setting and the second, the lower limit. Electrical limit switches are provided at each extreme of travel of the speed changer to operate signal lights for the benefit of the electrical control room operator. These switches are

Figure 2 (left). Speed governor located in turbine front standard

Figure 4 (below). Steady-state speed regulation

Figure 5 (A). Speed-power output curve with speed changer set to give rated speed at rated load

Figure 5(B). Steady-state incremental speed regulation

not intended to break the motor circuit, but built into the speed changer mechanism is a friction clutch which slips when either stop is reached. The speed changer motor is of a sufficient size that it only draws a fraction of rated current when either stop is reached and the clutch slips.

Manual Overspeeding

Built into the stop which provides the upper limit of governor setting is an overspeed button latch which permits the turbine operator to use the manual synchronizing handwheel to run the turbine under control of the governor right up to the tripping speed of the emergency governor simply by pulling up on the button and turning the handwheel beyond the upper limit stop. When the speed changer mechanism is turned back to the normal operating range, either with the manual handwheel or the motor, the stop button automatically relatches.

Speed Governing System Sensitivity

The sensitivity of the rotating pilot valve governor is kept to a maximum due to the continuous rotation of the element which tends to eliminate friction. The rotational effect tends to prevent foreign particles from lodging between the rotating pilot valve and the sliding bushing. The continuous flow of leakage oil through the close clearance between the pilot valve and bushing also contributes to washing away minute foreign particles as well as lubricating the two surfaces. Due to the high sensitivity of the governor, the speed governing system as a whole exhibits excellent over-all sensitivity.

Figure 3 shows a sensitivity chart taken by adapting a movable carriage to a photoelectric frequency recorder. Frequency changes are recorded across the chart and valve servo-motor piston movement is mechanically multiplied to position the carriage. A speed governing system which exhibits poor sensitivity or a considerable amount of dead-band would trace a wide loop on such a chart. It is the width of the loop that is the measure of the sensitivity of the system. This turbogenerator showed the speed governing system dead-band to be 0.03 per cent of rated speed. It should also be noticed that the steady-state incremental speed regulation is also shown by the average slope of the loop and may be calculated quite easily since the multiplied movement of the servo-motor piston is shown for a definite frequency change.

Steady-State Speed Regulation

The steady-state speed regulation on the rotating pilot valve governor may be adjusted easily with the turbine generator at rest by simply changing the relationship of the fulcrum point of the main sliding bushing restoring lever. A set of ten washers are provided at the adjustable fulcrum position capable of being arranged to give a steady-state speed regulation of from 2 to 6 per cent. In general, if the purchaser has expressed no preference, the governors are set to give a steady-state speed regulation of 3.5 per cent rated speed from zero power output to rated power output. Figure 4 is a typical curve showing this setting.

Steady-State Incremental Speed Regulation

Even though the speed governor and speed control mechanism are correctly designed, if proper consideration is not given to correctly designing the cams for lifting the governor-controlled valves, the speed governing system in general will not be satisfactory. Poor cam design can cause unequal amounts of load to be picked up for equal movements of the valve servo-motor. It is essential that cams be designed to give essentially a straight line characteristic of turbine power output versus valve servo-motor piston stroke. Even though great care is

exercised in the cam design, the steady-state incremental speed regulation will be increased at the intercept point of each valve. In the interest of turbine efficiency, it is desirable to lift a valve a sufficient amount to minimize the pressure drop through the valve before the next valve starts opening. Figures 5A and 5B show a very excellent job of cam design, and the steady-state incremental speed regulation varies but a small fraction of a per cent from the steady-state speed regulation, except at the intercept points and at the beginning of the number 1 cam which was designed in this fashion for easy synchronizing.

Overspeeding on Loss of Maximum Power Output

Contracts written for large turbine generators specify that the speed governing system be capable of operating sufficiently fast upon dropping maximum load from the unit so the terminal speed reached will not be high enough to trip the emergency governor. The emergency governors are in general set to trip between 110 and 111 per cent speed. With the growing trend to 3,600 rpm machines and larger capacities, the relative masses per kilowatt output of the turbine rotors and generator fields have decreased due to improved design refinements. The resulting smaller moments of inertia of the rotating parts with increased kinetic energy storage has resulted in much faster rotor acceleration upon loss of maximum load. On many large units, the rotors will accelerate in excess of 15 per cent overspeed in one second. This means that if the emergency governor were set at 10 per cent overspeed, the speed governing system would have to function sufficiently fast to close the governor-controlled valves in slightly less than 0.7 seconds. This problem would not be difficult if at the same instant the governor head felt the speed change, the servomotor began closing the governor-controlled valves. From a practical point of view this is impossible because each element of the speed governing system inherently possesses qualities that contribute to a lagging of one element of the mechanism behind the preceding device. Each additional increment of time makes the closing problem more difficult. Time is consumed in accelerating the weights of the governor head a sufficient amount to displace the governor rotating pilot valve an amount to cause the speed governor relay to dispell the oil under its piston at the maximum rate. More time is required to get the main pilot valve

Figure 6. Effect of entrained steam on turbine-generator overspeed

approximately 50 per cent open, so the maximum rate of oil flow into the closing side of the servo-motor will be realized.

Effect of Entrained Steam on Overspeed

Even when the control valves are actually closed, there is still a volume of steam in the turbine casing which will accelerate the unit. Figure 6 shows the effect of entrained steam on an 80,000 kw 1,800-rpm turbine-generator for a load dump of 96,000 kw. This entrained steam, in general, contains energy of a sufficient amount to cause one per cent overspeed. More entrained steam capable of feeding back into the turbine is contained in each feedwater heating extraction line. The energy storage of the entrained steam in all extraction lines from the turbine to the check valves in their respective lines cannot be permitted to exceed another one per cent overspeed if the speed governing system is to meet the contract requirements. A detailed study is made of the station extraction system to see if it will satisfactorily allow the contract commitments to be met. Recommendations are made for revised check valve locations if the entrained steam volumes exceed the allowable one per cent overspeed. In cases where an auxiliary steam source connects into an extraction line for feedwater heating purposes under low-load conditions, in general, it is required that a plain swing check valve be placed in series with a positive-closed check valve between the steam source and the turbine. It is felt that destructive overspeed would result on the turbine-generator if full load were dropped and a check valve failed to close. This is guarded against by the additional protection of the second check valve. The positive-closed check valve is required to be arranged for tripping by the emergency governor on overspeed of the turbine generator. The entrained steam problem may be further complicated by the omission of large cumbersome check valves difficult to justify in one or more low pressure extraction lines which feed closed feedwater heaters. In this case the entrained steam volume will include the steam in the extraction line from the turbine to the heater plus the steam storage in the heater shell proper. Any water stored in the heater presents a flashing problem and must be kept to a minimum. This effect may be decreased if the water is not stored in the heater shell proper but is contained in a drain cooler connected to the heater shell by a comparatively small pipe to limit the rate of flashing.

Briefly, the present practice of the turbine-generator manufacturer, represented by the writer, regarding the use of nonreturn check valves in extraction lines of nonautomatic extraction units, is as follows:

1. No check valve required. (When the total energy stored in the heater shell plus its extraction line is negligible. That is, the sum total of this energy plus the energy contained in all other extraction lines feeding back into the turbine will not cause an

Figure 7. Speed governing system speed-time lag for instantaneous loss of maximum power

overspeed on the unit in excess of one per cent upon loss of maximum load.)

2. One free swing check valve. (Used when a failure of this valve on loss of maximum load would result in a back flow into the turbine capable of accelerating the unit not in excess of 20 per cent overspeed momentarily.)

3. One positive-closed check valve. (Used when a failure of this check valve on loss of maximum load results in back flow from a limited energy source such as an open heater, evaporator, or deaerator, capable of causing a momentary maximum speed in excess of 120 per cent.)

4. One positive-closed check valve and one free swing check valve in series. (Used when there is a steady source of steam supply from a boiler, reducing station, boiler feed pump exhaust, or extraction connection from another turbine, capable of running the turbine continuously in excess of 120 per cent speed upon loss of maximum load.)

Effect of Speed Lag on Components of the Speed Governing System

Figure 7 shows an actual load dump test as recorded by oscillographs for this same 96,000 kw load dump.

This rotor only had a measured acceleration rate of 9.1 per cent overspeed per second, but it will give an accurate picture of the rotor acceleration and the various time lags between the elements of the speed governing system. During the time immediately following the load dump, the inertia of the governor, force lag of the weights, and position lag of the speed relay piston cause the speed governor to lag behind the ideal steady-state condition corresponding to the 3.4 per cent regulation for the speed changer nut setting. The speed governor lag, in turn, reflects upon the instantaneous position of the main pilot valve. The pilot valve was not unported sufficiently to have the servo-motor piston reach its maximum rate of acceleration until 0.275 seconds after the load dump. The speed governor had a maximum lag of 1.3 per cent speed at the beginning of the relay stroke and 1.85 per cent speed lag at the end of the stroke. When the speed governor pilot valve was effectively opened, the minimum lag was 0.73 per cent speed and the relay cylinder was closed 0.57 seconds after the instant of dumping the load. The valve servo-motor piston reached an acceleration equal to the rotor acceleration approximately 0.25 seconds after the instant of load dump and had a maximum lag of 3.5 per cent speed when the valve servo-motor reached its closed position. The valve servo-motor was closed 0.825 seconds after the instant of dumping the load. A maximum rotor overspeed of 7 per cent was measured with the rotor showing a slowing-up effect from the maximum acceleration rate 0.65 seconds after the instant of dropping the load.

The foregoing values represent a satisfactory governing mechanism performance for a turbine-generator whose rate of acceleration under maximum load condition is 9.1 per cent per second. For rotors having rates of acceleration up to 15 per cent per second, the lag of the valve servo-motor piston behind the governor speed relay piston, illustrated in Figure 7, may be required to be reduced. In double acting servo-motors, this may be accomplished by increasing the oil pump capacity and providing a larger servo-motor pilot valve. Reduction in time lag of the governor speed relay piston behind the rotor acceleration may also be required and can be readily accomplished.

Discussion

J. R. Norton (General Electric Company, Schenectady, N. Y.): The author's excellent paper is a well illustrated résumé of modern governor design. It is rugged and simple, yet sensitive to an extreme degree without sacrificing safety and reliability. The governor engineers are to be commended for a design which makes the turbine control device an accurate and reliable instrument.

The essentially constant incremental regulation, except at the valve cracking points, approaches the ideal governing so necessary for the economical operation of present-day large and interconnected generating stations. The near-linear response does much to alleviate the duty of automatic frequency controls. The minimum value of the three per cent incremental regulation insures good system stability, and the maximum values should not prove a hindrance to good automatic frequency control. The modern governor is a much needed development that will permit utility operators to take full advantage of the normal and maximum ratings of generators, transformers, and transmission lines. As the installed capacity of accurately governed prime movers approaches the optimum, the more easily block loading is accomplished, and the effect of fringe or unpredictable load swings is minimized.

The optimum in system regulation and tie-line load control can be hastened by a program to eliminate or improve inaccurate governors on major prime movers. Turbine manufacturers are doubtless ready to adapt to existing units this modern development so ably described to us.

Preliminary Considerations of System-Wide Load Division by Means of Accurate Time Control

T. E. CURTIS
ASSOCIATE AIEE

W. M. PICKSLAY
MEMBER AIEE

Synopsis: Generators and tie lines experience damped natural oscillations in response to load changes or other disturbances. The magnitude and duration of such oscillations is considerable when contemplating system-wide load division by means of accurate time control. A computing servomechanism is considered herein for high-speed resolution of phase angle conditions, whether oscillating or not, into a steady load order proportional to the causative load change. Transfer function analysis is included as an essential step in determination of stability of the proposed control system. Such analysis offers a clear picture of the related performance of computer, governor, penstock, turbine, generator, and tie line.

SOME of the attractive possibilities of load division by means of accurate time control have been discussed in earlier papers.[1,2,3] This paper enters further into the studies of the problems to be solved if such control is to be achieved. The method is outlined for theoretical determination of stability through transfer function analysis.[4,5]

Steady State Load Division

The nature of load division under consideration is recapitulated in Figure 1. In steady state, first and second derivatives ϕ' and ϕ'' are equal to zero, where ϕ is the phase angle in electrical radians between generating unit frequency f and primary frequency standard F. Subscripts denote number of generating unit with which the symbol is associated.

In the steady state, the computer outputs or load orders λ_1 and λ_2 are expressed only by $\lambda_1 = c\phi_1$ and $\lambda_2 = c\phi_2$. These are applied to the prime mover governors in such sense that the generator outputs are increased with increasing phase angle. If the generator phase angles are increasingly lagging, it is an indication of insufficient generator output for the connected loads.

Equating power flow at each bus with $G_1 = c\phi_1$ and $G_2 = c\phi_2$:

$$G_1 - L_1 + \frac{E_1E_2}{X_{1-2}} \sin\ (\phi_1 - \phi_2) = 0 \qquad (1a)$$

$$G_2 - L_2 - \frac{E_1E_2}{X_{1-2}} \sin\ (\phi_1 - \phi_2) = 0 \qquad (1b)$$

Assuming E_1 and E_2 are held at one per unit by voltage regulators, and $\sin\ (\phi_1 - \phi_2) = \phi_1 - \phi_2$ when $\phi_1 - \phi_2$ is less than 0.5 radian, equations 1a and 1b reduce to

$$G_1 - L_1 + \frac{\phi_1 - \phi_2}{X_{1-2}} = 0 \qquad (1c)$$

$$G_2 - L_2 - \frac{\phi_1 - \phi_2}{X_{1-2}} = 0 \qquad (1d)$$

The solutions of equations above are plotted in Figure 1, taking tie line reactance as 4 per unit on the base of the capacity of generating unit number 1, $c = 1$ (equivalent to each generator developing rated output at 1 radian lag behind F), L_2 steady at 1 per unit, and L_1 decreasing from 1 to 0.2 per unit.

For this case, approximately 20 per cent of the total load variation appears in the tie line. This would be decreased with higher tie line reactance or by a larger setting of c in the computer. Just how large a setting of c is feasible without resulting instability of control will need be determined by experience. However, it seems entirely practicable to limit the tie line variation to as low as 5 per cent of the change in load at one bus. This figure would be 50 per cent without load control equipment if governors at each terminal had the same droop.

The tie line load curve may be shifted by the addition[3] of Δ to $c\phi_1$ and $c\phi_2$. This is equivalent to adjusting the respective governors to a different division of loads when $\phi_1 = \phi_2$.

Transient Conditions

The previous presentation[2] of this governing system was based upon qualitative considerations primarily concerned with improvements anticipated in steady state load division among generators in an extensive interconnection. In the subsequent quantitative investigation, it has developed that the use of the computing servomechanism offers a further advantage not otherwise realizable, that the phase angle of a generator unit from a reference frequency may be controlled as desired without considerable unnecessary regulation of the gates due to the control trying to follow the instantaneous oscillations in phase angle which occur. The theoretical nature of these oscillations was described by Rüdenberg[6] and Warming.[7]

In Figure 2 (A and B) are reproduced representative 2-minute high-speed charts of the frequency variation experienced at one point in a large interconnection. The solid line shows the instantaneous deviation from 60 cycles, as traced from a frequency recorder chart with greatly expanded scale and suppressed zero. The dotted traces were secured by graphical methods from the solid trace and show the instantaneous rates of change of fre-

Paper 48-281, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted August 2, 1948; made available for printing September 17, 1948.

T. E. CURTIS and W. M. PICKSLAY are both with the Pacific Gas and Electric Company, San Francisco, Cal.

The authors wish to acknowledge their indebtedness to C. F. Merriam of the Pennsylvania Water and Power Company for data regarding high-speed recording of frequency variations in the Safe Harbor Hydro Development of the Safe Harbor Water Power Corporation at Safe Harbor, Penn.

Figure 1. Steady-state load division

quency and the accumulated frequency deviation.

Both curves were obtained in the Safe Harbor Hydro Development of the Safe Harbor Water Power Corporation on a weekday afternoon to secure a fair sample of normal conditions. Curves in Figure 2(A) were with five generators regulating system frequency with the New York tie open, at which time the estimated interconnected capacity was 5,000,000 kw. Curves in Figure 2(B) are with six generators regulating with the New York tie closed, giving an 11,000,000 kw interconnection.

Inspection of these curves shows that random oscillations in bus frequency occasioned by load disturbances are substantially sinusoidal, have a period of approximately 4 seconds and a time constant of 6 seconds, and are substantially the same whether or not the New York tie is closed. This indicates that, for practical purposes, the oscillations are expressible by equation 2. This equation may also be arrived at from logical considerations[8] of system characteristics.

$$J\phi_1'' + \delta\phi_1' + A\phi_1 = T_1 \tag{2}$$

Where

J = inertia constant of connected generators at Safe Harbor.
δ = damping factor.
A = spring constant equivalent to elastance of transmission links between Safe Harbor and the remainder of the interconnection.
ϕ_1 = angle in radians that generator voltage lags voltage of a 60-cycle reference frequency.
T_1 = per unit torque equivalent to load disturbance.

The purpose of the load order computer is to solve equation 2 continuously for T_1. Therefore, if the settings of a, b, and c in the computer are proportioned to the system constants J, δ, and A at the location of the computer, output λ will be a measure of the amount of load change which initiated the oscillation. If λ is applied to the governors, it will cause the local units to absorb the local load change immediately. This means that with computers installed at major generating stations, the effect of load changes would be restricted within the areas in which load changes occur, with transmission links remaining substantially unaffected.

Figure 3 approximates the observations of Figure 2 in terms of the second order linear differential equation 2. This approximation considers that the generators have 4 kilowatt-seconds stored energy per kilovolt-ampere capacity, and that the effective tie line reactance is 18.8 per unit from an infinite bus on the base of connected capacity at Safe Harbor. Factors a, b, and c, computed previously, are listed in Figure 3. Factor c is taken arbitrarily as 1.000 in order to provide load division similar to that shown in Figure 1.

Assuming a block change of a unit load torque as indicated in Figure 3, the resultant oscillations in ϕ, ϕ', and ϕ'' are calculated from the solution of equation 2. If the instantaneous values multiplied by the factors are added, the steady load order λ in the upper curve is obtained. The approximate transient response of the computer is indicated for a computer figure of merit $\beta = -6$. Note that whereas the computer would adjust the governor to the required new value in approximately 1 second without overshooting, a control responsive to phase angle alone would oscillate about the new required value for many seconds.

Computer Performance

A block diagram of the computer is included in the upper portion of Figure 4. Its transient performance is expressed by the differential equation

$$k\phi_1'' + h\phi_1' + \phi_1 = f_1(t) \tag{3}$$

where $f_1(t)$ represents any selected form of computer input. Factors h and k are determined as below for optimum operation of the computer. Equation 3 considers that the input servo has sufficiently fast response to keep the θ contacts operating about the neutral position, and that the contact spacing is negligibly small. For critically damped operation of the computer, it is necessary that

$$\sqrt{h^2 - 4k} = 0$$

The figure of merit of the computer is defined

$$\beta = -h/2k$$

To examine the response of the computer to a damped oscillation as indicated in Figure 3, consider that

$$f_1(t) = \frac{T}{A} - \frac{T}{B} e^{\alpha t} \cos(\psi t - \rho) \tag{4}$$

Where

A is a constant

$$B = \frac{A}{\sqrt{\alpha^2 + \psi^2}}$$

T = torque in per unit
α = damping factor in inverse seconds
ψ = natural frequency in radians per second
ρ = displacement angle in radians

The solutions of equations 3 and 4 are then

$$\phi_1 = \frac{T}{A} - \frac{T\beta^2 e^{\alpha t}}{B[(\alpha-\beta)^2 + \psi^2]} \times \cos\left(\psi t - \rho - 2\tan^{-1}\frac{\psi}{\alpha-\beta}\right) + (c_1 t + c_2)e^{\beta t} \tag{5}$$

$$\phi_1' = \frac{T\beta^2\sqrt{\alpha^2+\psi^2}}{B[(\alpha-\beta)^2+\psi^2]} e^{\alpha t} \times \sin\left(\psi t - 2\tan^{-1}\frac{\psi}{\alpha-\beta}\right) + (c_1\beta t + c_1 + c_2\beta)e^{\beta t} \tag{6}$$

$$\phi_1'' = \frac{T\beta^3(\alpha^2+\psi^2)}{B[(\alpha-\beta)^2+\psi^2]} e^{\alpha t} \times \cos\left(\psi t + \rho - 2\tan^{-1}\frac{\psi}{\alpha-\beta}\right) + (c_1\beta^2 t + 2c_1\beta + c_2\beta^2)e^{\beta t} \tag{7}$$

Where c_1 and c_2 are constants

$$\rho = -\tan^{-1}\alpha/\psi$$

Figure 2(A). Pennsylvania Water and Power Company tests

Figure 2(B). Pennsylvania Water and Power Company tests

$$\frac{\beta^2}{[(\alpha-\beta)^2+\psi^2]}$$

is computer amplitude factor

$$2\tan^{-1}\frac{\psi}{\alpha-\beta}$$

is computer lag angle.

These solutions show that the three outputs of the computer, before consolidation into the load order, all lag by the same angle the actual ϕ, ϕ', and ϕ'', respectively. The solutions also show that the computed amplitudes are all reduced from the respective actual amplitudes by the same fraction. The lag angle and the amplitude reduction both decrease as the figure of merit β is increased. The amplitude reduction may be compensated for by gear ratios in consolidating the three outputs into the single load order. It is important that all three outputs lag the actual values by the same angle, because this permits the resolution of the load order with a minimum "ripple."

Frequency Response of Computer

In order to examine stability of the entire control system by means of transfer function analysis, it is necessary to determine the response of the computer when

$$f_1(t) = \sin \psi t \tag{8}$$

where ψ is an assumed variable frequency expressed in radians per second. Equation 8 represents a steady state sinusoidal variation between f and F, such as might be caused by a small sinusoidal variation of the gate position, or by a small sinusoidal variation in the load torque.

The steady state solutions of equations 3 and 8 are

$$\phi=\frac{\beta^2}{\beta^2+\psi^2}\sin\left(\psi t-2\tan^{-1}\frac{\psi}{-\beta}\right) \tag{9}$$

$$\phi'=\frac{\beta^2\psi}{\beta^2+\psi^2}\cos\left(\psi t-2\tan^{-1}\frac{\psi}{-\beta}\right) \tag{10}$$

$$\phi''=\frac{-\beta^2\psi^2}{\beta^2+\psi^2}\sin\left(\psi t-2\tan^{-1}\frac{\psi}{-\beta}\right) \tag{11}$$

These solutions are multiplied by load order constants c, b, and a, respectively, and are plotted in Figure 5. The curves represent loci of vectors with respect to ϕ_o, the actual phase angle between f and F. For example, the $c\phi$ curve indicates that computer output $c\phi$ lags the actual phase angle ϕ_o by approximately 19 degrees when ψ is one radian per second. Computer output $a\phi''$ leads ϕ_o by nearly 180 degrees at low frequencies. The magnitude of $a\phi''$ increases and lead angle from ϕ_o decreases as ψ is increased.

Figure 3. Transient characteristics of generator, tie line, and computer

The vector sum of the three computer outputs is also plotted in Figure 5, and is represented as

$$\lambda=a\phi''+b\phi'+c\phi \tag{12}$$

The over-all output-over-input[5] transfer function becomes

$$Y_{(G)}=\frac{\lambda}{\phi_o}=\frac{(c\beta^2-a\beta^2\psi^2)+j\psi b\beta^2}{(\beta^2-\psi^2)-j2\psi\beta} \tag{13}$$

The family of vector diagrams represented by Figure 5 illustrates that λ may be made to pass through or near the origin at a selected frequency by suitable adjustment of constants a, b, and c. Such adjustment could be likened to "tuning" the computer to the natural frequency of the system. Figure 3 illustrates the optimum "tuning" to the damped natural oscillations which are characteristic of the system for particular conditions. It is noteworthy that ϕ, ϕ', and ϕ'' are separated by phase angles of 90 degrees in the steady state sinusoidal case, as compared to 96 degrees separation as indicated in Figure 3 for damped natural oscillations. The additional six degrees is represented by ρ in equations 5 and 7.

Governor Performance

In order to simplify the following loop transfer functions and the resulting system transfer functions, representative values for constants are inserted during the development.

Referring to Figure 4, the rate of change of relay valve displacement is proportional to the pilot valve displacement, that is

$$S'=K_1\epsilon$$

Assuming K_1 corresponding to unit relay valve displacement in one second and substituting $j\psi$ for the differential sign the loop transfer function becomes

$$\frac{S}{\epsilon}=\frac{1}{j\psi}$$

But the relay valve displacement is used as a cut off for the pilot valve as represented by the unit feedback loop. Therefore

$$\frac{S}{i}=\frac{S/\epsilon}{1+S/\epsilon}=\frac{1}{1+j\psi}$$

The rate of change of turbine nozzle opening is proportional to relay valve displacement, that is

$$G'=K_2S$$

Assuming unit nozzle opening in four seconds with the relay valve at unit displacement, then

$$\frac{G}{S}=\frac{1}{4j\psi}$$

and

$$\frac{MG}{i}=\frac{M}{1+j\psi}\frac{1}{4j\psi}$$

but

$$\frac{MG}{\lambda_c}=\frac{MG/i}{1+MG/i}=\frac{M}{(1+j\psi)(4j\psi)+M} \text{ or}$$

$$\frac{G}{\lambda_c}=\frac{1}{[(M-4\psi^2)+j4\psi]}$$

where $M=K_3D$ and K_3 is the linkage ratio between the droop setting mechanism and the pilot valve and D is the per unit droop setting.

The performance of the dashpot is characterized by the equation

$$x^1+\frac{x}{T_1}=RG'$$

where R includes all linkage ratios through

the dashpot up to the pilot valve. Assuming a dashpot time constant T_1 of one second and substituting $j\psi$ as before:

$$\frac{x}{G}=\frac{j\psi R}{1+j\psi}$$

Then

$$\frac{x}{\lambda_c}=\frac{x}{G}\frac{G}{\lambda_c}=\frac{j\psi R}{1+j\psi}\frac{1}{(M-4\psi^2)+j4\psi}$$

and

$$\frac{x}{d}=\frac{x/\lambda_c}{1+x/\lambda_c}=\frac{j\psi R}{(1+j\psi)(M-4\psi^2+j4\psi)+j\psi R}$$

But

$$\frac{G}{x}=\frac{1+jx}{j\psi R}$$

Therefore

$$Y_{(G)}=\frac{G}{d}=\frac{1+j\psi}{(M-8\psi^2)+j\psi(R+M+4-4\psi^2)} \tag{14}$$

This is the governor system transfer function. Considering flyball input as part of $b\phi'$, this is plotted in Figure 6 for $M=1$ and $R=50$. The complete formula without the substitution of numerical constants is

$$Y_{(G)}=\frac{K_1K_2(1+j\psi T_1)}{[MK_1K_2-\psi^2(1+K_1T_1)]+j\psi[K_1K_2T_1(R+M)+K_1-T_1\psi^2]} \tag{14a}$$

Penstock and Turbine

The deviation G in nozzle opening produces an acceleration or deceleration of the mass of water in the penstock. The corresponding force is balanced by the reaction of the jet, that is

$$\frac{\delta L_pA_pV_p'}{32.2}=-\delta A_jh \tag{15}$$

where

h = deviation in head in feet of water
δ = water density in pounds per cubic foot
A_j = jet cross section in square feet
A_p = penstock cross section in square feet
L_p = penstock length in feet

This equation assumes incompressible water and a rigid penstock and is permissible where

$$\frac{1}{\psi G}>\frac{4L_p}{V_s} \tag{16}$$

where V_s is the velocity of sound in water or approximately 4,700 feet per second.

Figure 4. Functional block diagram of hydraulic turbine governor with load order computer

Dividing both sides of equation 15 by V_oH and remembering that $A_j/A_p=1+G$, then

$$\frac{L_pV_o}{32.2H}v_p'=-h(1+G)$$

with v_p' and h now in per unit values.

Let

$$\frac{L_pV_o}{32.2H}=T_2 \tag{17}$$

where T_2 is the penstock time constant in seconds and V_o and H are initial penstock water velocity and head respectively.

After substitution

$$T_2v_p'=-h(1+G)$$

The jet velocity $V_j=\sqrt{2g(H+h)}$. However, we may assume $h=1.9V_j$ where the deviation in jet velocity from unit velocity is less than 0.1 per unit.

Then

$$T_2v_p'=-1.9\ V_j(1+G)$$

But

$$V_j=\frac{1+v_p}{1+G}-1$$

Therefore

$$T_2v_p'+1.9V_p=1.9G$$

or

$$v_p=\frac{1.9G}{1.9+j\psi T_2}$$

and

$$v_p'=\frac{1.9Gj\psi}{1.9+j\psi T_2}$$

In the per unit system we may say that $1+v_p=Q$ the penstock flow. Then

$$Q=1+\frac{1.9G}{1.9+j\psi T_2}$$

The deviation in head

$$h=-\frac{T_2v_p'}{1+G}$$

Substituting, multiplying numerator and denominator by $1-G$, and dropping terms in G squared permissable since G is assumed not to exceed 0.1 per unit, then

$$h=-\frac{T_2G1.9j\psi}{1.9+j\psi T_2}$$

and the total head

$$H=1-\frac{T_2G1.9j\psi}{1.9+j\psi T_2}$$

The power available in the jet is QH. This is also turbine torque at unit wheel velocity considering the turbine as 100 per cent efficient.

Since

$$QH = 1 + \frac{1.9G - j\psi 1.9T_2G}{1.9 + j\psi T_2}$$

again dropping terms in G squared.

The torque deviation

$$T = \frac{1.9G - j\psi 1.9T_2G}{1.9 + j\psi T_2}$$

and

$$Y_{(P)} = \frac{T}{G} = \frac{1.9 - 1.9j\psi T_2}{1.9 + j\psi T_2} \tag{18}$$

This penstock transfer function is plotted in Figure 8 with T_2 equal to one second calculated by equation 17 from representative data,[8] for a penstock 690 feet long with rated velocity and head of 10.25 feet per second and 213.5 feet of water respectively for a 70,000 horsepower turbine.

In the case of a steam turbine, there being little energy storage in steam flow, an entirely different transfer function would be found. This is not developed however since it presents an easier control problem than does a hydraulic turbine.

Generator and Tie Line

From inspection of equation 2, the generator and tie line transfer function is written

$$Y_{(B)} = \frac{\phi_0}{T} = \frac{1}{(A - J\psi^2) + j\psi\delta} \tag{19}$$

This is plotted in Figure 6 with values for J, A, and δ corresponding to the computer constants a, c, and b respectively shown on Figure 3 so as to simulate the conditions at the Safe Harbor hydro plant.

Complete Loop

The complete loop transfer function is the vector product of the individual transfer functions, that is

$$[Y_{(C)} + Y_{(F)}]\,Y_{(G)}\,Y_{(P)}\,Y_{(B)} \tag{20}$$

where $Y_{(F)}$ is the transfer function of the governor flyballs.

Present day governor heads have time constants on the order of 0.05 seconds or less, corresponding to approximately three degrees lag at one radian per second. The inertia of the flyballs may then be neglected and the flyball transfer function written as:

$$Y_{(F)} = \frac{Z}{F - f} = \frac{j\psi}{377 \cdot W} \tag{21}$$

where W is the per unit deviation in frequency required to produce unit pilot valve displacement and 377 radians per second corresponds to unit speed.

Assuming W as 0.15 per unit, the magnitude of this transfer function is 10 per cent or less of the computer transfer function, depending on ψ at the point considered. Since the addition is made vectorially, $Y_{(C)} + Y_{(F)}$ is only slightly different from $Y_{(C)}$. Also this small difference may be compensated for by reducing the value of b in the computer proportionately since $b\phi'$ corresponds to Z in effect.

Consequently $Y_{(F)}$ may be neglected and the over-all loop transfer function reduces to

$$Y = Y_{(C)}\,Y_{(G)}\,Y_{(P)}\,Y_{(B)} \tag{22}$$

This is the vector product of the individual transfer functions of Figures 5, 6, 7, and 8, and is plotted in Figure 9.

Since the locus falls inside of the -1 point, the system is stable. The effective damping ratio and degree of stability may be estimated from the radius of the circle, centered on the -1 point, which is tangent to the output vector locus.[4] This circle is shown in Figure 9. In the present example, the effective damping ratio is approximately 0.2. This is as low a damping ratio as can be permitted. The ratio can be increased by increase in the value of R associated with the governor dashpot.

The speed of response of this control should be adequate since the over-all gain is not reduced far below one until a frequency ψ of four to five radians per second is reached. This is well beyond the frequency of the oscillations measured at Safe Harbor. However, for abnormal conditions where large and rapid increments of generation may be required, it may be advisable to increase this response automatically by means of a pressure relief valve in the governor dashpot. Such a relief valve would open only in response to large abrupt changes in the load order.

Inspection of Figures 5 and 9 reveals that the effective damping ratio can be increased also by a decrease in the setting

Figure 5. Frequency response of load order computer

Figure 6 (right). Transfer function of generator and tie line

of b. This action may be visualized by remembering that Figure 9 indicates that the closing of the control loop causes a slight change in the frequency of oscillation and in the effective damping.

Summary

For certain assumed conditions, it has been shown that the computer output is proportional to the load torque initiating the oscillations in generator phase angle. However, if the natural frequency of the oscillations change because of relaying or change in generation in a controlled area, the proportionality factor will change and there will be a ripple in the computer output. As change in generation or transmission connections would be at dispatcher's instructions, such instructions could include setting the computer accordingly. This should not be onerous as dial settings for factors a and b may be determined in advance for each normal system setup.

In the case of relaying, the ripple in the computer output would only delay the restoration of steady state load division. However, the change in the generator and tie line transfer function will modify the stability and a sufficient margin of stability for expected relaying must be incorporated in the governor settings. If the controlled generation should become isolated, infinite tie line reactance, the system becomes absolutely unstable and the computer must be automatically disconnected leaving the governor alone in control.

The tests at Safe Harbor, Figure 2 (A and B), indicate relative absence of other frequencies in the oscillations of generator phase angle. This might be expected since such other frequencies must arise from remoter controlled areas. The presence of the inertia of the nearest controlled area would be expected to damp out such frequencies before they reach the point under discussion. Other frequencies present to a limited degree however would only modify the computer output slightly. This would affect stability, but could not result in hunting since the transfer function analysis shows the system to be stable at any frequency.

Since the computer gain is so much greater than that of the flyballs as indicated by the ratio of their respective transfer functions, it is necessary to increase the lever ratio between gate motion and the dashpot to secure stability. This may require modification of the standard hydraulic governor though a less pessimistic development or experience may show that present adjustment ranges are adequate.

If the adjustment range should need material extension, an additional dashpot which could be disconnected when control is returned to the governor would be desirable. An alternate not requiring dashpot modification would be the use of mechanical or electrical lead networks associated with the computer. Use of electrical lead networks for stabilization in this regard has been discussed by Chestnut.[8]

The foregoing development assumes a governor built for 5 per cent droop. All mechanism ratios are considered reduced to a per unit basis, so that a steady one per unit change in the load order will cause a steady one per unit change in generation. If it is found desirable to retain the flyballs in an installation, their contribution should be co-ordinated with the computer so that the effective $b\phi'$ yields performance as indicated in Figure 3.

The transfer analysis brings to light a hitherto not generally recognized point. It is granted that the inertia represented by the volume of water in the penstock is usually much larger than that of the turbine and generator. However, from the regulation point of view, the combination to the penstock, turbine, and generator is only twice as difficult a problem at most as compared with the turbine and generator alone as may be seen from inspection of the plots of Figures 6, 8, and 9. It is actually the generator and tie line transfer function that principally determines the gain at 180 degrees total phase shift since it shifts nearly 90 degrees for a change of frequency from 1.3 to 1.7 radians per second. The major importance of the hydraulic inertia remains in the determination of permissibles rates of gate motion without physically endangering the penstock and associated structures.

It will be noted that the over-all loop transfer function is plotted with a dashpot time constant of one second whereas previous experience would dictate an optimum value of about seven seconds. Inspection of equation 14a shows that with R so large, T_2 appearing in both numerator and denominator has relatively little effect. In this case R is large to secure

Figure 7. Transfer function of governor

Figure 8. Transfer function of penstock and turbine

Figure 9. Complete loop transfer function

stability against an infinite bus. An infinite bus is normally a fiction but in this case is physically realized since generation elsewhere on the system is controlled similarly. That is the controls function to maintain a fixed frequency irrespective of load.

For simplicity of analysis, it has been assumed that the generator shaft and terminal voltage angles are one and the same. Further study will be necessary to evaluate the relative merits of computer input from shaft angle versus generator terminal voltage. It would appear though that the extra complication of obtaining shaft angle would not be warranted.

It may be argued that a control of this sensitivity will result in excessive operation of the governor and gate or nozzle mechanisms with corresponding increased wear and maintenance. From an overall point of view though, it should result in less rather than more individual regulating operations since each governor will only need respond to load changes in its own area. Where such control is not used, every unblocked governor on the system must respond to every load change on the system excepting only those of such small magnitude as to call for a load change less than the governor sensitivity as may occur at a regulating unit on the system periphery.

Conclusion

A phase angle control comprised essentially of a computing servo-mechanism which produces a load order proportional to load changes in a controlled area is entirely practicable from theoretical consideration of test data. Such control would not involve major changes in existing equipment, would be far more sensitive than present controls, will improve steady state load division among units in an interconnected system, minimize tie line load fluctuations, and permit operation closer to stability limits. Such control may be stabilized readily except in the event a unit becomes isolated.

It is possible that interconnections may be held intact through greater disturbances, since the proposed control system will initiate accurate corrective action at high speed. Such a control system could operate intelligently even though separation into parts did occur.

Equations have been presented which permit calculation of specific cases. Solutions of these by means of a differential analyzer would give further insight into the operation. Failing such analysis, the next step requires trial of such control on an actual system.

Discussion

C. K. Duff (Hydro-Electric Power Commission of Ontario, Toronto, Ont., Canada): The proposed control system is a daring concept demanding unprecedented sensitivity in the control equipment and speed of response on the part of controlled generators. Admitting the sensitivity of the proposed control equipment and its ability to produce a load order proportional to load changes in a controlled area, the form which this load order takes, and the manner in which it is to be applied to conventional governors to secure the necessary speed of response without major changes in existing equipment, have not been made clear. If as implied in Figure 4 of the paper, control is applied at the same point as manual control and other automatic controls are commonly applied, the usual handicaps of governor deadband, sluggishness due to dashpot damping, and nonlinear power-gate characteristic of the turbine combine to frustrate the effort to obtain prompt and proportional load response to a given load order.

According to Curtis' earlier paper,[1] the normal band of phase deviation appears to be about $^1/_{60}$ second or 360 electrical degrees (60 cycle). To contain deviations within this narrow band would certainly require high speed response from regulating generators. If these are hydroelectric units, and if means were employed to overcome governor sluggishness, and so forth, for example by operating directly on the pilot valve, water inertia in the penstock would tend to defeat the purpose by producing in the first few seconds a change in torque opposite to that which is intended. Although the authors deal with penstock and turbine constants mathematically, it is not clear whether this characteristic effect of water inertia has been allowed for. For the same reason it seems debatable whether such high-speed control would assist or oppose stability of hydroelectric systems under fault conditions.

Figure 2 of the paper is confusing, in that time apparently runs left to right in the upper diagram but right to left in the lower one. A corresponding diagram for the Southern Ontario System of the Hydro-Electric Power Commission of Ontario is shown in Figure 1 of the discussion. Only the instantaneous frequency and integrated frequency or phase deviation are shown, and though measured on the 25-cycle system, the results are shown in terms of equivalent 60-cycle values. The interconnected area has roughly 2,000,000 kw of generating capacity. The record was taken at Toronto at 6:22 p.m. on Tuesday, August 10, 1948. The swings of frequency are due to load swings from a hot strip mill at Hamilton, 40 miles west of Toronto. The load increases in about 10 seconds to 20,000 kw peak which is maintained about 10 seconds, then drops off in 10 seconds or less. Automatic frequency control of a comparatively slow-acting type

Figure 1. Frequency and phase deviations. Southern Ontario system of The Hydro-Electric Power Commission of Ontario. Swings are due to load cycle of a hot strip mill located 40 miles from the point of measurement

was in service, controlling three generators of 40,000 kw capacity each at Queenston plant, Niagara Falls. The frequency swings are not visibly changed by cutting off the frequency control.

It will be noted that phase deviations are in the order of ±400 degrees or more which means that the system is outside the normal 360-degree band most of the time. This is perhaps a bard case but it occurs normally several hours each day. The rate of load change, about 2,000 kw per second, could probably be matched by the Queenston generators without endangering the penstocks, but not through the medium of the standard governor controls with normal governor damping. Although interconnection with larger systems would reduce the magnitude of the frequency and phase-angle swings it would not appreciably reduce the duty on the local generators and regulating equipment for area control, otherwise the swings would appear on the tie-line load.

The new control system aims to reduce load fluctuations on tie lines as illustrated in Figure 1 of the paper, but a tie-line deviation still exists and seems to require a minimum droop of perhaps five per cent, for stability. To secure flat tie-line control, which is often desirable, an automatic slow-acting bias might serve. This, it would seem, would necessitate telemetering if the tie-line metering points were remote from the control stations.

The proposed new system of control would not work in conjunction with any existing load-frequency control such as that which is now in extensive successful use. A new system to displace an existing one would need to have convincing superiority not only in theory but also in actual results under practical operating conditions. Some of the practical aspects seem to require further study and tests, especially the problem of converting a load order into a load response with existing facilities.

H. W. Cory (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The authors are to be commended for undertaking the analysis of a hydroelectric system by means of transfer functions of the components of the system and the Nyquist diagram of the complete system to indicate stability.

Of particular value, and not readily apparent from the paper, is the use of the tangent circle about the $-1, 0$ point on the Nyquist diagram to indicate damping ratio or a measure of the system stability.

The analysis given depends on the computing mechanism giving continuous control. In this connection what amount of backlash is present in the θ contacts? The amount of dead band caused by these contacts would appear to make the control discontinuous if of any appreciable magnitude.

What would the difficulty be in obtaining the constants for equation 2 for a given system under varying tie line connections and generation capacity?

What rates of load pickup would be required or expected on units controlled by the system described?

Would it be feasible to use a central frequency standard with a signal distributed to all stations controlled by the system rather than depending on separate frequency standards for each station?

Has consideration been given to the stability at light load versus full load for a given setting of the computer and to the effect of nonlinearity of the various elements of the system on the calculated stability?

T. E. Curtis: Duff has raised a number of questions which merit detailed consideration, even beyond the scope of the paper or this closure. Regarding the application of the load order, the authors were thinking in terms of a low-energy synchro output signal from a centrally-located computer. Individual governors would be adopted with conventional synchro follow-up devices. Alternatively, each governor could be equipped with a direct-acting computer.

In reply to questions regarding water inertia and dashpot damping, careful study of Figures 7 and 8 of the paper should make the situation abundantly clear. Nonlinearity of power-gate characteristics were not considered in the paper in view of data in reference 8 which indicates that they may be neglected.

Duff is correct in noting the error in the plotting of Figure 2 (A and B). The corresponding diagram for the Southern Ontario System is most interesting, and it would be very desirable to interpret the data into an estimate of performance under the proposed system of control. Obviously, such an estimate would require knowledge of detailed constants of the system. Also, as indicated in the paper, solution of the equations would probably require the assistance of large scale computing devices. Such solutions would indicate whether or not the anticipated superiority of operation would merit full-scale tests.

Cory has asked five excellent questions. In reply to his first question, control is actually discontinuous by definition, but may be regarded as continuous in that the spacing of the θ contacts merely represents an error between calculated and actual ϕ. Tests of the computer indicate that it may be desirable to make the θ contacts "dither" continuously.[1] Regarding the second question, constants for equation 2 can be determined from logical consideration of particular data. It is true that resolution of data for a large interconnection may become difficult, although Figure 2 (A and B) illustrates that the actual change of constants may be very small even for major changes in the interconnection capacity.

Regarding the third question, load pickup would necessarily be determined by prime mover limitations, ranging from nearly instantaneous in some steam cases to one minute from no load to full load in hydroelectric installations. Attention is invited to the difference between gate servomotor response and load change rates dictated by penstock pressure rise. It is the gate servomotor response which must be considered in transfer function analysis of stability. Regarding the fourth question, it would be feasible to use a central frequency standard. An installation of this nature is described in reference 2. It would probably be more satisfactory and economical to use independent frequency standards at controlling power plants, since commercially-available primary frequency standards now have sufficient stability to remain substantially in synchronism with each other over long periods of time. Independence from the vagaries of communication systems would thereby be obtained.

Regarding the fifth question, the paper described the problem under what appears to be the most difficult conditions for stability. Nonlinearity of penstock performance is perhaps the most important nonlinearity present in the system, and its effect is worse at full load. At lighter loads, Figure 8 would retain the same shape, but values of ψ would shift counter-clockwise so that the lag angle would be reduced at a particular frequency. Other nonlinearities, such as power-gate and turbine efficiency characteristics, and dead band, have been neglected. The effect of dead band could be introduced into the calculations following the approach of reference 3 of this closure.

Credit for the first proposal of system-wide load division by means of accurate time control belongs to H. C. Forbes and F. Zogbaum.[3] It is believed that this paper advances the concept to preliminary quantitative terms. Much work remains to be done before the application stage can be achieved.

Application of Low Frequency to Industrial Control Problems

N. L. SCHMITZ
ASSOCIATE AIEE

THE PURPOSE of this paper is to consider a means of operating an induction motor at slow speeds in a manner analogous to that of a d-c motor supplied from a small low-voltage generator. Motor characteristics at low voltages and low frequency are analyzed and extended to the special case of direct current. The problems involved in generating polyphase low-frequency voltages of useful magnitude are set forth and their solution by means of single-phase self-excited a-c commutator-type generators is described.

Motor Characteristics with Constant Flux Density

At normal voltage and frequency the voltage drop in an induction motor due to primary resistance and leakage reactance is relatively small, about 3 per cent and 7 per cent, respectively, of normal voltage at full load. Consequently the generated electromotive force (back emf) and flux are essentially constant in magnitude for wide changes in load. Such is not the case when we reduce the frequency and impressed voltage. Although the generated electromotive force and leakage reactance drop decrease in proportion to the frequency, the resistance drop (for any given load current) remains constant. Thus at 3 per cent frequency and at full load the resistance drop is of the same order of magnitude as the generated electromotive force. In order to maintain normal flux under this condition it is necessary to increase the impressed voltage until it exceeds the generated electromotive caused by normal flux at 3 per cent of normal frequency by an amount sufficient to compensate for the resistance and reactance drop. Assuming that flux is held constant in this manner, torque is expressed by the relation:

$$T = K_1 \phi I_2 \cos(\phi, I_2)^* \tag{1}$$

where

$$I_2 = \frac{K_2 \phi \omega_2}{\sqrt{r^2 + \omega_2^2 L_2^2}} \tag{2}$$

$$\cos(\phi, I_2) = \frac{r_2}{\sqrt{r^2 + \omega_2^2 L_2^2}} \tag{3}$$

Substituting equations 2 and 3 in equation 1

$$T = K \phi^2 \frac{\omega_2 r_2}{r^2 + \omega_2^2 L_2^2} \tag{4}$$

From the above relation we see that the torque depends only upon ω_2 for any given motor and flux. Hence, for any given motor and flux, the rpm difference between shaft speed and synchronous speed is fixed for a given torque. Thus, decreasing the frequency while maintaining constant flux shifts the speed torque characteristic *A* in Figure 1 downward, parallel to itself, to produce characteristic *B*.

Motor Characteristics With Constant Impressed Voltage

Since it is not practical to maintain the flux density constant, we must devise a means for predicting the torque characteristics under the more usual condition of constant impressed voltage. At normal frequency this can be done quite accurately by means of the ordinary equivalent circuit of the induction motor. However, when we wish to show the effect of varying the frequency of the impressed voltages, it is more convenient to use equation 30 derived in Appendix I:

$$T = 3 V_1^2 \frac{M_0^2 r_2}{[rR - \omega_1 \omega_2 (L_0 l_0 - M_0^2)]^2 + [\omega_1 r L_0 + \omega_2 R l_0]^2} \tag{30}$$

This relation can be obtained by regarding the primary and secondary windings of the induction motor as comprising two inductively coupled circuits and calculating the torque in terms of winding resistances, self inductances, and mutual inductance.

As the impressed frequency is decreased, the primary current becomes less dependent upon the load conditions of the motor. Therefore, the magnitude of the no-load current approaches that of the full-load current. This may be seen from equations 29 and 32 in Appendix I. From this we see that for an impressed voltage corresponding to normal full load current, secondary frequency, and torque, the magnetizing current at no load will exceed its normal value to an extent determined by the reduction in frequency. This is of no serious consequence because even though the magnetic circuit is to some extent saturated, hysteresis and eddy current losses are not excessive when the frequency is low. We can thus achieve a normal slip-torque relation from no load to full load torque by decreasing the primary voltages in somewhat less than a direct proportion to the frequency. As would be expected, however, for loads greater than normal, the primary current does not increase as rapidly with low frequencies as with normal frequency. Consequently, the maximum torque is less than would be obtained at normal frequency.

The maximum torque can be increased by raising the primary voltage at the expense of increased no load currents, but the final decision must be made on the

basis of duty cycle, torque requirements, and allowable speed variation.

Methods of Generating Polyphase Low Frequency Power

Many schemes have been investigated. Among these are:

1. Synchronous generators running at low speed.

Figure 2. Methods of obtaining low frequency alternating voltages

(A) Reversing contactors; (B) Motor driven potentiometer; (C) Alternate discharge of capacitors (C_1 and C_2) F_1 and F_2 are low frequency output terminals; L_1 and L_2 are d-c supply lines

2. Frequency changers similar to a slip ring motor.

3. Polyphase commutator machines.

4. Single-phase commutator machines suitably interconnected to give polyphase voltages.

In methods 1 and 2, the generated voltage is directly proportional to frequency and speed. Consequently, large, slow speed machines are required for even moderate power output at frequencies of 2 to 5 cycles. In method 3, relatively small, high speed machines can be used, but as in all polyphase rotating machines, the field of flux rotates in space and consequently there is no fixed neutral axis for commutation. In some machines of this type, (such as the "ohmic drop exciter")[8] the frequency of the output voltage is proportional to the difference between synchronous speed and shaft speed. Since both these quantities are large, any slight change in shaft speed causes a large percentage change in output frequency.

Figure 3. Self-excited low frequency generator with transformer coupling

(M) Driving motor; (G) Commutator type generator; (T) Coupling transformer; (L_1 — L_2) Power source for applying momentary d-c starting pulse

These difficulties are not insurmountable as evidenced by the practical application of a polyphase commutator machine in generating frequencies of 2.5 cycles.[2]

The advantages inherent in single-phase commutator machines are relative independence of frequency with changes in load, and the existence of a neutral commutating axis. The single-phase generator may be either self excited or separately excited. Among the methods of separate excitation are:

1. Motor driven potentiometer.

2. Reversing contactors.

3. Alternate discharge of oppositely charged capacitors.

Figure 4. 'Bucking bronco' motor-generator connection

(M_1) Driving motor; (G) Series generator; (M_2) Shunt motor; (L_1 — L_2) Separate excitation for M_2

These methods are illustrated in Figure 2. The motor driven potentiometer may be so proportioned as to give a sine wave of exciting current. This feature can also be approached in method 3 by selecting capacitors which will provide series resonance with the generator field inductance at the required frequency. Even with relatively low voltage field circuits, low resonant frequencies can be obtained by using electrolytic capacitors for this purpose. Although these illustrations apply to single-phase excitation, they may also be used to excite several generators in a polyphase system. For example, in Figure 2(B) another pair of brushes b_3 and b_4 can be mounted at right angles to brushes b_1 and b_2 so as to excite the field of a second generator in a 2-phase system.

Self Excitation of a Single-Phase Generator

In all of the foregoing methods of excitation, the commutator machine served as an amplifier to magnify the low energy control signal and provide useful power output. If the machine can serve as an amplifier in the same manner as a 3-element vacuum tube, we might also expect it to function as a feed-back oscillator.[9] Self excitation may be accomplished through either inductive[7] or capacitive coupling.

The method of inductive coupling shown in Figure 3 has some of the features of a relaxation oscillator. An initial d-c starting current causes the generator to build up a voltage which causes an aiding electromotive force to be induced in the secondary of transformer T. This continues until the rate of voltage increase declines as a result of magnetic saturation either in the generator field or in the transformer. The exciting current decreases, causing a reduction in voltage and a reversal of the cycle. Because of the relatively large size transformer required at low frequencies, capacitive feedback has proved more economical.

Capacitive feedback for a single-phase machine was proposed as early as 1920.[10] It has also been familiar as a laboratory curiosity in the "bucking bronco" motor shown in Figure 4. In Figure 4, the capacitor C shown in Figure 5 has the form of a separately excited shunt motor with its brushes connected in place of the capacitor terminals. The generator (which is usually a d-c series machine) is driven at a constant speed and causes the shunt motor to accelerate until its back electromotive force exceeds that of the generator, whereupon the series field excitation reverses, in effect "plugging" the shunt motor until it reverses rotation and begins the opposite half cycle.

By employing a shunt generator and a static capacitor in the manner outlined before we obtain a constant potential, low frequency source of single-phase power. Connections are shown in Figure 5. The efficiency of the generator may be increased by laminating its field structure to reduce eddy current losses. Voltage regulation and commutation are improved by adding compensating windings to neutralize armature reactance and prevent field distortion. The system can be made self starting by using the CR relay, shown in Figure 5, to shunt the capacitor with a low resistance whenever the generator voltage is less than 70 per cent. This prevents demagnetizing the field when the generator is shut down and allows the machine to build up as a d-c shunt generator when starting. With these improvements, a practical source of low-frequency power is obtained.

Polyphase Power from Single-Phase Machines

Polyphase power may be obtained by employing two single-phase generators having their field currents displaced 60 degrees. When a "V" connection is employed as shown in Figure 6(A) a 3-phase system is obtained. With this connection the generator field circuits have conjugate impedanced, as shown in the vector diagram Figure 6(B). We may dispense with exciter E if we use one of the main generators to supply both field circuits as shown in Figure 7.

Figure 9. Instantaneous currents and voltages with generators connected as shown in Figure 6

(A) Generator voltages and currents; (B) Load currents

Impedance drop in generators G_1 and G_2 may cause minor voltage unbalance due to unequal impedance among the three phases. This can be avoided at the expense of an additional generator G_3 by using connections as shown in Figure 8.

Test Results

A small scale polyphase low-frequency power system was built in accordance with Figure 6. The generators were two 1/5-horsepower 32-volt commutator-type machines driven by a 1/2-horsepower squirrel cage induction motor. The exciter was a similar 110-volt commutator-type machine. This combination was used to successfully "inch" and "thread" four 1-horsepower 220-volt induction motors either individually or simultaneously in a model printing press drive. Static torque was set between 150 and 200 per cent of rated full load torque for each motor. Figure 9 shows the instantaneous currents and voltages obtained under full load conditions.

Summary

The performance of an induction motor on low-frequency voltages is readily predictable by means of the relations shown in Appendix I. We find from these relations that full torque is available from the motor providing the impressed frequency is at least equal to the slip frequency at which this torque would normally occur. The change in speed from full load to no load under the foregoing conditions is approximately the same as under normal operating conditions.

Small high-speed machines can be effectively employed in generating the voltages needed for low-frequency operation. Although the generating system which we have described is best suited to supplying one frequency, a selection of frequencies and speeds can be obtained by simultaneously switching the relatively low current exciting circuits to provide the necessary change in circuit constants for different frequencies.

Speed control in the manner described is particularly useful in applications requiring several induction motors to be started either individually or simultaneously without immediately accelerating to a high speed. This feature is required in printing press and other drives where a number of individual units are flexibly interconnected. The ease with which these units can be arranged in various combinations is greatly enhanced if they can be individually driven. Ordinary wound rotor induction motor control does not provide the required slow threading speeds and the use of individual gear shifting or other mechanical speed changers complicates the mechanical system. The use of a low-frequency power source is one solution to this type of problem.

Appendix I

Derivation of Speed-Torque Relations.

Using the general equations derived by Stanley[1] we can express torque in terms of speed, primary frequency, and motor resistances and inductances.

$$T_1 = -\frac{3}{2} I_\alpha M_0 i_\beta + \frac{3}{2} I_\beta M_0 i_\alpha \tag{20}$$

$$I_\alpha = \frac{V_1}{Z_1} + \frac{V_2}{Z_2} \tag{21a}$$

$$I_\beta = \frac{-jV_1}{Z_1} + \frac{jV_2}{Z_2} \tag{21b}$$

$$i_\alpha = \frac{(p-jn)M_0}{r+(p-jn)l_0}\frac{V_1}{Z_1} - \frac{(p+jn)M_0}{r+(p+jn)l_0}\frac{V_2}{Z_2} \tag{21c}$$

$$i_\beta = j\frac{(p-jn)M_0}{r+(p-jn)l_0}\frac{V_1}{Z_1} - j\frac{(p+jn)M_0}{r+(p+jn)l_0}\frac{V_2}{Z_2} \tag{21d}$$

$$Z_1 = R + pL_0 - \frac{p(p-jn)M_0^2}{r+(p-jn)l_1} \tag{21e}$$

$$Z_2 = R + pL_0 - \frac{p(p+jn)M_0^2}{r+(p+jn)l_0} \tag{21f}$$

The foregoing equations are for instantaneous, torque and current quantities, and the impedances shown are transient impedances. If we express V_1 and V_2 as vector quantities and replace the differential operator p by $j\omega_1$ we obtain the corresponding steady state relations. Equation 20 yields the average torque if we perform the multiplications $I_\alpha i_\beta$ and $I_\beta i_\alpha$, using the product of their rms values and the cosine of their phase difference. Thus equation 20 becomes

$$T = \frac{3}{2} M_0 [-I_\alpha i_\beta \cos(I_\alpha, i_\beta) + I_\beta i_\alpha \cos(I_\beta, i_\alpha)] \tag{22}$$

In the case of balanced primary voltages, $V_2 = 0$, and the quantity, $p - jn = j\omega_2$, is the rotor frequency.

With the above simplifications we may substitute equation 21a in equations 21b, 21c, and 21d to obtain

$$I_\beta = I_\alpha \angle -90 \text{ degrees} \tag{24}$$

$$i_\alpha = I_\alpha \frac{\omega_2 M_0}{\sqrt{r^2+\omega_2^2 l_0^2}} \angle 90 - \tan^{-1}\frac{\omega_2 l_0}{r} \text{ degrees} \tag{25}$$

$$i_\beta = I_\alpha \frac{\omega_2 M_0}{\sqrt{r^2+\omega_2^2 l_0^2}} \angle -\tan^{-1}\frac{\omega_2 l_0}{r} \text{ degrees} \tag{26}$$

Since

$$\cos\left(-\tan^{-1}\frac{\omega_2 l_0}{r}\right) = \frac{r}{\sqrt{r^2+\omega_2^2 l_0^2}} \tag{27}$$

We may substitute equations 24 to 27 in equation 22 to obtain

$$T = 3 I_\alpha^2 \frac{M_0^2 r \omega_2}{r^2+\omega_2^2 l_0^2} \tag{28}$$

The above relation shows the variation of torque with respect to rpm slip for the case of balanced primary currents. A corresponding expression for the more usual case of constant, balanced primary voltages may be obtained by solving for I_α by substituting equation 21e in 21a.

$$I_\alpha = V_1 \frac{r + j\omega_2 L_0}{(rR - \omega_1\omega_2 L_0 l_0 + \omega_1\omega_2 M_0^2) + j(\omega_1 r L_0 + \omega_2 R l_0)} \tag{29}$$

Substituting 29 in 28

$$T = 3 V_1^2 \frac{M^{02} r \omega_2}{[rR - \omega_1\omega_2(L_0 l_0 - M_0^2)]^2 + [\omega_1 r L_0 + \omega_2 R l_0]^2} \tag{30}$$

For the special case of direct voltage applied to the stator, both 28 and 30 reduce to

$$T = 3 I_\alpha^2 \frac{M_0^2 r \omega_2}{r^2+\omega_2^2 l_0^2} \tag{31}$$

and 29 reduces to

$$I_\alpha = V_1 \frac{r + j\omega_2 l_0}{(rR + j\omega_2 R L_0)} = \frac{V_1}{R} \tag{32}$$

Appendix II. Symbols

ϕ = airgap flux (mutual flux)
T = average three-phase torque in synchronous watts (based upon normal frequency)
T' = instantaneous torque
I_2 = secondary current
ω_1 = primary frequency in radians per second
ω_2 = secondary frequency in radians per second

Discussion

John F. H. Douglas (Marquette University, Milwaukee, Wis.): Low frequency has been used since 1910 to produce stroboscopic flicker, since 1915 for electric hammers, since 1925 for starting stabilizing gyroscopes, and now for inching and threading. I have been fortunate to be in on some of these tests, and wish to record that it now appears to be a must for teachers.

Concerning the induction motor behavior my tests confirm those of Schmitz. However it should be mentioned that with low frequency and high stator IR drop, saturations become rather high at light load.

Concerning methods of generation of low frequency. Doctor Bennet should discuss the oscillating machine, and some General Electric man should state the capabilities of the brush-shifting 3-phase commutator machine as a frequency changer.

The author's method of analysis, although powerful, using the primitive machine axes, and differential operator, does not adequately cover nonlinearity, and the oscillograms show distorted wave form. Any self-excited machine must of necessity depend on saturation for no-load voltage stability.

Some remarks on how to demonstrate low frequency effects in the college laboratory may be in order. Almost any laboratory can demonstrate them with existing equipment.

If 15 cycles are desired laminated yokes and poles are necessary, but compensated machines are not necessary. If 5 cycles are sufficient, laminated poles and solid yokes can be used, but with solid poles and yokes one cycle is about the limit.

When eddy currents are present Schmitz' paper must be modified somewhat. First, the d-c saturation curve is higher than the a-c curve. Second, the effective resistance of the shunt field is so high that the field must in general be multipled. Third, armature voltage and field current are not in phase, owing to the angle of hysteretic and eddy current advance.

The shunt commutator machine will run as an adjustable speed motor. Thus there are many problems ideally suited to the college laboratory.

Jerome M. Frank (Hevi Duty Electric Company, Milwaukee, Wis.): An interesting comparison of equation 31, concerning the torque developed when a direct voltage is applied to the stator, was given in a paper presented in December 1943 by Alfred Oklund before the Milwaukee section of the AIEE on Direct Current Breaking of Induction Motors. Oklund's analysis and correlating test data have proved very valuable to various manufacturers in the Milwaukee area, who are interested in the calculation of the torque obtainable at various speeds when a direct current is applied to the stator.

Oklund first developed the relationship between the stator and rotor magnetomotive forces, the winding constants and the direct current to be applied, by the vector addition of the first harmonic magnetomotive forces of all the active stator coils. From this he established the amplitude of the flux density in the stator and rotor. The rotor was calculated in terms of the stator so that the constants could readily be obtained from tests. He then related the direct current to its equivalent alternating current in terms of the rotor and stator flux density. From the equivalent circuit of an induction machine, it was then possible to relate the equivalent alternating current to the measured constants of the machine. For a given direct current and a constant magnetizing reactance, saturation neglected, the voltage impressed on the rotor was shown to be constant and the rotor current could then be calculated. By substituting in the basic torque formula for the rotor current, the value of rotor current obtained before, he derived an equation showing that the torque was directly proportional to the number of phases, the square of the stator current, the square of the magnetizing reactance and the rotor resistance and inversely proportional to the sum of the rotor resistance squared and the square of the sum of the magnetizing reactance and the rotor reactance. This equation is similar to that derived by Schmitz.

Oklund's equation has an advantage in that the calculations are very easy to perform as the equation is in terms of the motor constants, which are readily available from a design or a test sheet.

It was very unfortunate that the untimely death of Alfred Oklund prevented his presentation of this masterpiece of engineering analysis before a general meeting of the Institute. The writer has arranged with Dr. John F. H. Douglas, of Marquette University, Milwaukee, Wis., to furnish mimeographed copies of Oklund's paper to those interested in it.

N. L. Schmitz: The writer concurs with Douglas as to the need for a consideration of low frequencies in teaching electrical machinery courses. By starting with a simple, inductively coupled equivalent circuit and using the appropriate self and mutual inductances, general expressions can be obtained for various currents and torque in most a-c machines. Since they are not limited to any one frequency, the relations thus obtained can be used to show behavior on any desired frequency, including the special case of direct current. When this is done for an induction motor, the results are the same as obtained by the somewhat more rigorous method of Appendix I. If the $j\omega$ operator is used in place of the differential operator in writing the circuit equations, the analysis can be carried out even though the student does not have a background in differential equations.

As pointed out by Douglas, the vector diagrams shown in the paper are based on the assumption that hysteresis and eddy currents in the generator field windings are negligible in relation to the magnetizing current.

Such is usually the case with high-grade well-laminated core materials. In the event that these currents are appreciable, a minor adjustment of the circuit constants suffices to shift the total field currents to a new phase position that their magnetizing components occupy the position now occupied by the total currents.

When the a-c shunt-connected commutator machine runs either as a motor or as a generator, the voltage induced in the armature coils contains a lower and a higher frequency component. These frequency components are due to the two components of the single-phase field rotating, respectively, with and against the armature. This imposes limitations similar to those of a-c series motors regarding iron losses and induced voltages in the armature.

I consider myself fortunate to have heard Oklund present his inspiring analysis of d-c braking. His work has done much to improve the concepts of induction motor behavior on both direct and low frequency currents.

Dynamic Lowering D-C Hoist Control

D. L. PETTIT
ASSOCIATE AIEE

THIS PAPER is intended to cover a specific scheme of dynamic lowering hoist control applicable to a series type motor. It is not intended to cover the study of performance of a d-c series wound motor, but a short review may be appropriate. Figure 1 shows a typical characteristic curve for a series wound motor. Of particular importance is the fact that such a motor tends to a runaway condition as torque is removed from its shaft. The dynamic lowering circuit circumvents this condition by separately exciting the series field so that the motor functions more nearly as a shunt motor when the speed is reasonably stable with variations in load.

The application of dynamic lowering is not new. Various circuits are in existence to accomplish this function. The details of such circuits are usually quite complex and vary considerably in accordance with the individual originating them. In order to obtain the required features, more contactors are required than in the conventional reversing circuit, more electrical interlocking is necessary and the application of mechanical interlocking is quite limited. The circuit described in this paper makes use of a minimum number of contactors and produces extra safety features not heretofore offered in dynamic lowering design.

Basic Considerations

A series motor is normally used in order that high torque may be developed to lift heavy loads. For hoisting a slack cable a point is introduced by using a shunting resistor across the field and armature to obtain a low-torque low-speed characteristic. This may also be used to obtain low-speed light-hook operation.

The shunting resistor may then be removed, possibly in steps, to produce increases in speed in the hoisting direction. Series resistors are also short circuited in order to reach the full-speed full-load condition.

For dynamic lowering, the field is excited by current drawn from the line through a current-limiting resistor, while the armature is connected to low-voltage points obtained by a potentiometer method, using the field circuit for the main path of the potentiometer.

Such an arrangement makes it possible to stabilize the speed in lowering, so that when the heavy loads deliver power back through the gear mechanism to the motor, this power is dissipated by conversion to electric power and dissipated in the field and resistor circuit. At the higher speed, part of the power may be returned to the line.

In order to assure adequate torque at the low speed, a strong field is provided. This current, usually in excess of full load current, is permitted to pass through the series brake so that positive release of the brake is obtained.

The lowering speed is increased in three ways. Additional resistance may be inserted in the armature circuit, permitting the armature to operate at a higher voltage and consequently higher speed. The armature may be connected across points in the potentiometer circuit which are at a higher potential, thereby increasing the voltage across the armature and, in turn, the speed of the armature. The field strength may be weakened, thereby requiring a higher speed of the armature in order to produce the proper counter electromotive force. This latter is particularly necessary in order to obtain high-speed light-hook lowering condition, wherein the usual requirement is to obtain at least 200 per cent of full load speed for lowering. Herein lies one of the principal advantages of the dynamic lowering system since it speeds up operation of the hoist thereby increasing its productive effort, and at the same time eliminating the attending maintenance problems that are involved in the application of load brakes.

The series brake is conventionally employed as it offers the greatest safety. Since it is spring set, it introduces safe failure in the case of voltage or current failures. It is, of course, necessary to pass sufficient current through the brake on the first point hoisting and the first point lowering in order to assure prompt and positive release of the brake. On subsequent higher speed points, it is only necessary to maintain adequate current through the brake coil in order to hold it in the released position. The series brake gives a safe condition in the event of a voltage failure which might be introduced by the tripping of an overload device, the opening of a fuse or circuit breaker, or failure within the power distribution system itself.

In order to enhance the control which the operator has over the hook load, the first few speed points on the master should involve smaller changes in speed than those near the high-speed positions. Since heavy loads on the hook have a tendency to spread out the low-speed points in lowering, and light-hook conditions spread out the low-speed points in hoisting, designs which incorporate lower speed increments at lower speed permit operators to handle light and heavy loads with almost equal dexterity.

When the master is moved from point to point, current peaks should be held to a minimum in order that the life of the controller and the life of the motor commutator may be prolonged.

It is advisable to incorporate automatic acceleration so that operation of the master switch handle too rapidly will not produce undesirable results. These time delays are considered necessary in connection with acceleration of the motor,

Paper 48-284, recommended by the AIEE industrial control committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted August 2, 1948; made available for printing September 16, 1948.

D. L. PETTIT is with the industrial controller division of the Square D Company, Milwaukee, Wis.

but not in connection with deceleration. Of particular importance is this point with regard to decelerating the load when lowering. In this condition, the motor must not only absorb the energy which the load is delivering back through the gear mechanism to the motor under a steady-state condition, but it must also produce the necessary torque to decelerate the load when the operator desires to slow down the lowering speed. No time delays are to be provided in this decelerating action as such time delays might take control away from the operator just when it is needed most. The operator must retain control of this deceleration even though it becomes necessary to decelerate at a rate which overtaxes the motor or the hoist mechanism. Such overtaxing may be preferable to damage which might result if the load could not be brought to a stop quickly.

Analysis of Functions

The circuit under consideration employs nine contactors and six resistor sections excluding the hoist limit stop. Figures 2 and 3 show the load and resistor circuit connections employed for each speed point. Since the dynamic lowering requirements govern the circuit design, its study will be first.

A field current between 100 and 200 per cent is obtained by a series parallel connection on a first speed lowering. The actual current in the field circuit is dependent upon the hook load. The armature is connected across the field itself through two parallel circuits, each of which consists of a resistor section and a spring-closed contactor. This circuit imposes a very low voltage across the armature. This low voltage when combined with the strong field established produces a low speed for the first lowering condition. Notice that the series brake carries all the line current in order to insure prompt and positive lifting of the brake.

Smooth action on the first lowering speed is obtained by appropriate choice of the ohmic value of the resistors in series with the armature. Since the time constant of the field prevents the field strength from being established instantly, the momentary torque of the motor in the downward direction is limited by these resistors to such a magnitude that transient overspeeding before the steady-state condition is reached is prevented.

Speed increases in the downward direction are obtained by a unique circuit, making use of a bridge resistor system, controlled by two spring closed contactors. Extra resistance is inserted in the armature circuit for the second lowering speed by removing one of the shunt paths in series with the armature. This permits the load to accelerate the armature to a higher speed.

A bridge circuit is established in the third speed increasing the voltage across the armature which, in turn, increases the lowering speed. The remaining spring closed contactor is opened to obtain the fourth lowering speed, leaving the armature connected to the resistor network in such a way as to further increase the voltage in the armature circuit which, in turn, further increases the lowering speed. Transfers through these speeds is attended with a closed loop at all times, containing the armature, the field, and some resistors so that regenerative power can be dissipated even though voltage failures may be encountered.

The armature is then transferred to line voltage to obtain speed 5. This is accomplished by closing contactor *2M* after the opening of contactor *2A*. It will be noted that the reverse order of operation of these two contactors would produce considerably higher current peaks since the reverse order would involve both of them being closed at the same time, thereby short circuiting a considerable portion of resistor network and would draw heavier current for the field momentarily as well as the armature. The opening of contactor *2A* first permits a resistance transfer minimizing the current peaks and thereby enhancing both commutator life and contactor life. In the steady-state condition for the fifth speed, the armature is essentially at line voltage and the field is excited at slightly less than the full load current. Only resistor 4 is in the armature circuit. This resistor serves to limit the current peaks as the transitions are made.

Pneumatic timers are employed in the transfers between speeds 4 and 5, and 5 and 6. Notice that the timing is so arranged that the transfer from speed 4 to 5 can be made immediately if operation has been maintained in speed 4 sufficiently long for the required timing period to have elapsed.

Speed 6 employs a weak field and is obtained by inserting resistance in the field circuit. Automatic control is imposed in the form of a current relay and a time delay. Relay *LR* closes its contact if the armature current exceeds a certain value. If its contacts are closed, contactor *1M* cannot be opened. By setting relay *LR* to function at between one quarter and one third of full load current, the operator cannot transfer to speed 6 unless the hook is lightly loaded. The time delay is imposed so that transient condition will have subsided in speed 5 before relay *LR* is permitted to open contactor *2M* for speed 6. If the master is

Figure 1. Typical characteristic curve for a series wound motor

Figure 2. Step by step load circuits

Figure 3(a) (left). Composite load and control

Figure 4 (above). Typical speed curves

moved quickly all the way into the full-speed lowering condition, this timer serves to provide automatic acceleration. Notice that the circuit is so arranged that once the contacts of *LR* have opened to insert the extra resistance 3, transient reclosing of *LR* has no further effect on the circuit.

In returning to lower speeds, speed 5 is obtained by increasing the field strength reducing the speed of the armature in much the same manner as is obtained with a shunt motor when the field is increased.

Speed 4 introduces the bridge circuit again. Contactor *2A* closes first as the speed is reduced, immediately followed by the opening of *2M*. The field is thus first strengthened while contactors *2A* and *2M* are closed at the same time, leaving only resistance 1 to limit the field current. This strong field tends to increase the counter voltage of the armature which, in turn, tends to deliver more current into the resistor network so that when contactor *2M* opens, a reduction in current has already started relieving the load which the contactor must open.

Speed 3 is obtained by permitting one of the spring closed contactors to close, reducing the voltage across the armature and thereby lowering the speed. Notice that since only one of these spring-closed contactors closes in this condition, the higher resistance value serves as a peak limiter.

Speed 2 is obtained by opening contactor *2L* leaving the armature connected through one resistor directly across the field. A further reduction in speed is obtained by permitting the remaining spring-closed contactor to close its contact, reducing the resistance in the armature circuit by the extra parallel path.

In the "off" position, the armature, the field, and the two parallel resistor sections are connected in such a way as to regenerate power and produce dynamic braking in the event of the failure of the voltage source or the spring set brake. Such an arrangement limits the lowering speed in the event of voltage and brake failure so that runaway speed and attending damage to personnel, equipment, and property is avoided.

Figure 3(b). Contactor sequence

Salient Features

Two spring-closed contactors employed in this manner produce particularly desirable results. Speed transfers are obtained with current peaks held to reasonable limits with the attending reduction in maintenance both on the controller and the motor itself. The connection of these contactors in parallel paths permits the use of contactors one size smaller than are employed in the remainder of the circuit since the currents in the regeneration circuit are usually of the order one-half of the full load current of the motor. Two contactors arranged in this fashion give extra safety. Since it is important that regenerative circuit be maintained under all circumstances to insure safe failure, the connection of these two contactors in this manner can be more fully appreciated when it is considered that the parallel contactor and resistor circuit so arranged are much more remote in the possibility of failure than one contactor and one resistor circuit in comparison.

Consideration of motor instability are quite important in dynamic lowering. A weak field must be guarded against when heavy loads are involved as instability may introduce a runaway condition and its attending damage. Relay *LR* is used to prevent such conditions. Test work in connection with this control and a ball-bearing test rig indicate that speeds in excess of 200 per cent of full load might be developed with a weak field when lowering with full load on the hook without passing the point of instability. Varying performance characteristics found among the different motors and different hoist mechanisms, particularly with regard to the efficiency of the hoist mechanism, make it necessary to be cautious in the approach to the point of instability. A safe consideration is to employ a field strength approximately that of full load as a minimum field for heavy hook conditions.

It will be noted that the brake is connected in the circuit so that it is required to carry all the line current on the first point lowering, but on subsequent points it carries only the field current. Such an

Figure 5. Effects of changing resistor values

arrangement prevents overheating of the brake coil, but yet assures positive releasing of the brake on the first point.

Similarly, the brake is required to carry the shunt current as well as the motor current on the first point hoisting to insure prompt and positive lifting of the brake shoe. However, if the motor is permitted to operate under a light-hook full-speed hoisting condition, the current may subside to a low value. If the brake is not properly chosen, it may reset at this low value and cause annoying reduction in speed in the operation of the hoist. Mill and plant engineers should particularly be cautious to select brakes in accordance with the motor data and thereby eliminate this type of difficulty.

The same set of resistors are used to obtain the hoisting speeds. The shunt circuit across the armature and field produces low-voltage conditions giving a low-speed point for taking up the slack in the cable.

In speed 2 one of the parallel paths in the shunt is removed to give an increase in light hook speed for manipulating light loads. In speed 3 a simple series connection is developed with a resistance for torque and speed limitation.

Speeds 4, 5, and 6 are obtained by reducing the amount of resistance in series with the motor by shorting and parallel arrangement. The paralleling of paths is accomplished for speed 5 by paralleling resistors 2 and 3. In speed 6, the motor and its series field are directly connected across the line.

Typical speed curves are shown in Figure 4. These speed curves were obtained by actual test data using a 45 horsepower, Westinghouse, type *K* motor in a test rig involving a 10-ton load. In examining these speed curves, notice that at least two low speeds are obtained for light hook manipulation in hoist direction and that at least three speeds below 100 per cent are involved for light hook lowering. More effective use is made of the speed points as the load is increased so that at 100 per cent load, at least three operating speeds are useful in the hoist direction.

Lowering speed 2 is actually a transfer speed. At light loads, this speed may be approximately equal to the first speed lowering while at extremely heavy loads it may approach that of number 3 lower. For intermediate values of load it gives intermediate speed between 1 lower and 3 lower, making it possible to obtain four useful operating speeds for heavy hook conditions, each of which are below 100 per cent. For heavy loads, a high speed in excess of 100 per cent is obtained in speed 5, while the sixth speed is locked out and is useful for light hook only.

The effects of manipulating the resistor values is shown in Figure 5. Resistor changes in the field when using a network system are minimized, as the bridging system produces better control of the hoist speed without regard to the motor characteristics. Resistors 5 and 6 may be unbalanced to secure differing responses for the second hoist and second lowering speed. The ohmic value of the motor armature and commutating field may require slight changes in resistor 4 in order to produce the proper slope to the lowering speed curves. The weak field high-speed light-hook condition is controlled by resistor 3. Since the saturation curve of the motor determines the strength of the field necessary to produce this high-speed condition, some adjustment of resistor 3 may be necessary in order to produce optimum performance of the hoist and motor combination. The usual cautions are necessary in connection with maintaining secure terminals and tight connections to the resistor banks. Extra resistance due to poor connections or loose terminals may considerably alter the performance of the motor and hoist combination.

Interpretation of the speed curves for the test setup would not be complete without a reminder that the efficiency of the hoist mechanism has the effect of moving the point on which the motor is considered to operate on these speed curves. In the test data the armature current for full-load lowering was slightly in excess of one-half that for hoisting full load. If the hoist mechanism were more efficient, the lowering current in the armature would be more and would have the effect of moving out farther on the lowering curves, producing slightly greater speed. If, on the other hand, the mechanism were less efficient and the armature current were reduced for similar load values, the operating point would

be moved to the left on the speed curve. Since exact performance cannot be predicted accurately, hoist users must expect that the speeds obtained may vary somewhat from those indicated in this discussion. Variations in speed will also be governed by the amount of overloading or underloading of the motor with regard to the hoist to which it is applied.

Contactors *1M* and *2M* relieve each other in their duty cycle so that neither is permitted to heat excessively. The amount of relief each gives the other is dependent upon the operation of the hoist in its various speeds.

The hoist limit switch is indicated as the conventional load type of limit with a self-contained resistor. A discussion of this unit is not included in this paper.

Drifting downward may be encountered in the low-speed hoisting when heavy loads are being manipulated. Operators customarily pass through the low-speed points quickly when handling the heavier loads. The drifting condition may prove quite useful when spotting heavy loads as it gives a means of lowering at extremely low speeds.

No time delays are incorporated for decelerating the load either for hoisting or lowering. For hoisting such time delays would serve no useful purpose as lower speeds are obtained by inserting resistance in the circuit, but for lowering, time delays may or may not be useful. Such delays are considered the exception rather than the rule as the operator must have complete control of the load in order to prevent accidents, damage, or injury under unforeseen circumstances. It is considered preferable to overtax the motor and the controller with heavy current peaks rather than risk danger to life or property.

Oscillograms shown in Figures 6 and 7 indicate current peaks for hoisting and lowering. Decelerating curves were obtained by rapid motion of the handle from full-speed lowering to the "off" position. Low commutating peaks are indicated as well as low values of current which the contactors must make and break.

Conclusion

The dynamic lowering scheme presented herein involves the use of a minimum number of nine contactors to obtain a six-speed system. Low commutating peaks within the controller minimize maintenance in connection with the contactors. Low accelerating peaks of current minimize maintenance of motor brushes and commutator. Added safety in operation is obtained by the use of two paths for regenerative current, greatly reducing the possibility of contactor, resistor and circuit failure and resultant runaway condition. Maximum re-use of resistor sections is practiced throughout the operation of the controller, minimizing the physical space requirements for the resistor. By reusing resistor sections, their design approaches that of continuously rated, thereby giving them a greater operating reserve in capacity.

Discussion

J. W. Cooke and G. W. Heumann (General Electric Company, Schenectady, N. Y.): The author has presented an interesting paper on a crane hoist controller, the outstanding feature of which is the efficient utilization of contactors and resistor sections for obtaining required hoisting and lowering operating characteristics. The controller described contains many desirable features. However, there are several points on which we should like to comment.

One of the fundamental principles to be considered in the design of a dynamic braking hoist controller is the maintaining of a field-armature loop circuit under all operating conditions lowering. Control equipment is subject to wear and maintenance, and even with the best design and manufacture such failures as breakage of a control wire, failure of a master switch contact, burnout of a contactor coil and so forth have to be considered as possible causes of incorrect controller performance.

In Figure 3 of the paper, dynamic braking contactors *1DB* and *2DB* are under direct control of the master switch contacts without any apparent interlocking with other contactors. When the master switch is notched to point 4 lower or beyond, contactors *1DB* and *2DB* are open. The loop around the motor armature is thereby removed, regardless of whether or not the other contactors have operated in proper sequence. For example, if contactor *2L* has not closed on account of a coil burnout, a wire breakage, or the like, the motor armature circuit would be open with the series brake released, resulting in loss of dynamic braking torque and overspeeding of an overhauling load.

The sixth point lower provides for a weak field connection for lowering light loads. A current relay *LR* automatically maintains a stronger field on this point if the load exceeds a certain predetermined amount. It is noted that relay *LR* operates in conjunction with normally open contactor *1M*. Should this contactor fail to close, heavy loads would be lowered under a weak field condition and excessive speeds would result. It appears to be preferable to use a spring-closed contactor for weakening the field for high-speed light-load operation.

Figure 2 of the paper indicates that on points 5 and 6 lower the motor is connected as a straight shunt motor with the field and armature circuits with their respective resistor sections connected straight across the constant-voltage line. In a paper which had been presented previously before the Institute[1] it has been pointed out that such a connection results in a lower stability limit than is obtained by the addition of a block of resistance in series with the line.

The speed-torque curves given in Figure 4 of the paper showed straight lines for points *5L* and *6L*. As the torque is expressed in per cent hook load, a full evaluation of these curves would require a knowledge of the loading of the motor with respect to its rating. The author mentions tests made with a 45-horsepower motor on a 10-ton hoist, but as no information is given on the speed of the load, it is not possible to evaluate what the load values represent in terms of motor torque. The straight-line curves for points *5L* and *6L* do not show any approach of a stability limit, and it would be interesting to know where the stability limit is to be expected.

In Figure 1 of the paper are shown the characteristic curves of a standard *MD612* series motor. This motor is rated 75 horsepower, 60 minutes. On an average crane installation this motor would be applied on the basis of its 100 horsepower, 30 minutes ability. Speed-torque curves have been calculated for this motor, using the formulas developed in the previously cited paper,[1]

$$T = KI_A \qquad S = \frac{E}{K}$$

where

T = per unit torque
I_A = per unit armature current
S = per unit speed
E = per unit electromotive force
K = a factor, expressed in per unit, designating torque per ampere and volts per revolution

Base quantities for the *MD612*—100 horsepower—30 minute motor are

T = 1,215 pound feet
I_A = 372 amperes
S = 433 rpm
E = 204.7 volts
K = 3.27 pound feet per ampere or 0.474 volts per rpm

Factor K of the *MD612* motor, as taken from test data, is given in Figure 1 of this discussion as a function of field and armature current. It will be noted that K varies greatly with changes in armature current at low field currents. Because of this inherent motor characteristic, the speed-torque curve for constant field excitation during lowering cannot be straight lines. Shown in Figure 2 of this discussion are calculated speed-torque curves for various amounts of motor field current with field and armature circuits connected across a 230-volt line. A value of 0.15 per unit resistance has been assumed to be in series with the armature. The amount of armature resistance determines the speed at which the stability limit occurs, but it has no effect on the maximum retarding torque the motor is capable of producing.

At the bottom of Figure 2 of this discussion motor torque and hook load have been correlated on the basis of the following assumptions: Motor base torque is required for hoisting full load on the hook. A driving torque of −0.10 per unit is required to lower the empty hook. At normal load, the hoist has a mechanical efficiency of 85 per cent so that lowering full hook load requires 0.7 per unit motor torque and, correspondingly, twice full hook load corresponds to 1.4 per unit motor torque.

A comparison between the author's curves and the calculated curves brings out several apparent discrepancies. The author states that curve *5L* is obtained with a field current slightly below full load current. He indicates a no-load speed of 120 per cent and a full load speed of 140 per cent. The calculations indicate that the field current of the *MD612* motor has to be reduced to 0.70 per unit to obtain comparable speeds. Under this condition the stability limit occurs slightly beyond twice normal hook load.

The author's curve *6L* indicates a no-load speed of approximately 175 per cent. Calculations show that it is necessary to reduce the *MD612* motor field current to 0.3 per unit to obtain such a speed. Under this condition the speed-torque curve is very unstable with the stability limit occurring at approximately full hook load.

It would be interesting to have the author's comments on the apparent discrepancies between the speed-torque curves of Figure 4 of the paper and Figure 2 of this discussion.

Figure 1. K-curves for *MD612* series motor, in per unit, based on 100-horsepower 30-minute ability

Reference

1. Dynamic Braking Control of D-C Series Motor—Calculation of Stability Limit, G. W. Heumann, W. P. Smith. AIEE Transactions, volume 65, July 1946, pages 454–57.

D. L. Pettit: Cooke and Heumann have presented a very well prepared discussion in connection with this paper. Their discus-

sion brings out points which well deserve covering.

A premise necessary in the design of a dynamic lowering circuit is that compromises in design are necessary to arrive at an appropriate solution. These compromises have to do with the practical limitations of the equipment and introduction of neutralizing measures which in themselves compromise the desirable characteristics of the control.

The control scheme presented represents a version of this network system which is characterized by simplicity and a minimum of equipment. Other variations are used where the conditions of the application indicate emphasis on certain features.

A coil burn-out of *2L* actually will open the armature circuit when the master switch is in positions 4, 5, or 6. This is not particularly alarming in most instances since the load would have been moving downward at approximately full-load hoisting speed or faster even if contactor *2L* were closed. Return of the master to positions 3, 2, or 1 recloses the regenerative circuit and brings the load under control. The net result is that the operator must be depended upon to return the master to a lower speed. If he does not do this, an unsafe condition will develop regardless of whether or not *2L* operated.

For those cases of extreme hazard, interlocking of *2L* and 1 *DB* contactors can be provided so that 1 *DB* does not open if *2L* does not pick up. This acts to keep 1 *DB* resistor loop intact in the regenerative circuit.

Regarding the comment on the failure of *1M*, it will be noted that should it fail to close, the motor will not be energized in speeds 1, 2, 3, and 4 lower. Hence the hoist will be inoperative in these points. When the master is moved to speed 5 or 6, contactor *2M* is closed. The field current may be so low as to not release the brake. The high-surge current to the armature through resistance 4 which is a very low ohmic value, will cause the overload to trip the under-voltage relay. Again, the crane becomes inoperative. Under these conditions, the crane operator is expected to call for maintenance. These conditions are considered safe.

In a variation of this circuit, we have already furnished an arrangement wherein the relay *LR* limited the lowering connection to the circuit for number 4 speed lower when heavy hook loads were involved. This in effect takes advantage of the improvement of stability limits by keeping a block of resistance (resistors 2 and 3 in parallel) in series with the line. This has the effect when extremely heavy overloads are involved of requiring the current returning to the line to flow through the resistor, raising the effective voltage above line voltage across the field and armature, thereby strengthening the field to improve the stability.

Figure 2. Dynamic braking lowering speed-torque curves for *MD612* motor for various amount of field excitation in shunt connection, based on 100-horsepower 30-minute ability

In the test data taken, full-load hoisting speed was 67 feet per minute. Actually, the points of data taken for the speed curves were not on an absolutely straight line, but no noticeable drooping of the curve was noted for values of hook load as indicated in the curves. Practical limitations of the setup limited further increases in loading.

In some cases, hook loads may reach values where stability limits are approached. As is borne out by the discussions, these stability limits are found at values of double or triple full load ratings. These cases deserve special consideration. The use of *LR* to limit the connection to speed 4, the reduction of ohmic value of resistance 3, or the complete neutralization of relay *LR* to eliminate weak field are considerations which should follow.

Direct comparisons of the stability limits cannot be made since tests were not conducted on an *MD612* motor. The actual motor used was a Westinghouse type *K* having a 30 minute rating of 45 horsepower. For purposes of comparison, a check with the test data indicates that on speed 5 at no-load speed per unit value of field current was 0.79 and on speed 6, it was similarly 0.41. When interpreting, allowance should be made for the difference in motors as well as possible errors in obtaining data.

The occurrence of the stability limit at about 200 per cent for speed 5 points up the advisability of using speed 4 for the limits for the operator if extreme abuse of the hoist is anticipated.

Relative Surface Voltage Gradients of Grouped Conductors

M. TEMOSHOK
ASSOCIATE AIEE

WITH the tendency toward higher a-c transmission line voltages, due to greater distances of power transmission and larger blocks of power transmitted, the type of line conductors to be used becomes of increasing importance. As the next voltage level above 287 kv evolves, the voltage gradient problem becomes more difficult. As conductor surface voltage gradients directly affect corona loss, the ultimate problem is that of corona loss. Increasing the conductor diameter is a solution; grouped conductors, two or more per phase, offer another solution.

To determine the degree grouped conductors affect the conductor voltage gradients is the aim of this paper. The approach is purely analytical, with the intent to indicate relative voltage gradients on conductor surfaces of grouped conductors to guide actual tests, and by comparison with actual tests, to determine the possibilities of calculating corona losses of grouped conductors. Major undertakings in the study of grouped conductors have begun in Sweden, France, Germany, and in this country.[1–6]

It is not the intention of this paper to cover the subject of inductance and capacitance values as affected by grouped conductors. The subject is introduced to present a more comprehensive and coordinated picture of the effects of grouped conductors, with regard to parameters and the effect on voltage gradients. The use of grouped conductors carries with it an important gain in the appreciably lower value of surge impedance, as the inductance of the line decreases and the capacitance increases. With the lower surge impedance and greater stability, a larger load may be carried.

Factors studied as affecting voltage gradients at the surface of the conductors are: number of conductors per phase; spacing between conductors of a group; spacing between phases; size of conductors; height above ground; presence and location of ground wires; and instantaneous values of voltages of each phase.

Assumptions

1. (*a*) All conductors are smooth.

(*b*) The area in circular mils is determined from the assumed smooth outside diameter of the wire, regardless of the construction, whether it be aluminum, copper, aluminum-steel, expanded, hollow, or solid. On any one comparison, the conductors are assumed to be geometrically similar.

2. Height of conductors and ground wires are assumed an average value over the span.

3. The line is perfectly transposed (for inductance and capacitance calculations).

4. Effects of line towers are ignored.

5. Spacing between phases is the distance between the centers of the conductor groups.

6. Intragroup conductor spacing is the distance between conductors of the same group.

7. Only the horizontal configuration of the line was studied.

8. (*a*) Two ground wires were used in the studies involving ground wires.

(*b*) Location of the ground wires was symmetrical with respect to the center and end phases.

(*c*) The ground wire protective angle was assumed to extend to the center of the conductor groups.

9. Unless otherwise specified, the term voltage gradient designates the maximum voltage gradient at the conductor surface.

10. Voltages are 60-cycle peak voltages unless otherwise specified.

11. Grouped conductors has been selected as the term applying to more than one conductor per phase. A study of literature in this field reveals the following terms used synonymously: bundle; split; multiple dual, duplex, triple (when two or three conductors per phase are used).

Scope of Study

1. Grouped conductors, groupings of 1, 2, 3, and 4 conductors per phase, with configurations as indicated by Figure 1:

2 conductors—horizontal configuration
3 conductors—triangular configuration
4 conductors—square configuration

2. Spacing between phases varied from 22 to 45 feet.

3. Intragroup conductor spacing varied from 8 to 24 inches.

4. Height of conductors above ground varied from 320 to 800 inches (26.67 feet to 66.67 feet).

5. Ground wire protection angles varied from 31 degrees to 45 degrees with one case extended to 90 degrees.

6. Conductor diameters were such as to keep the total conductor area per phase constant; conductor diameter ranges were:

1 conductor per phase—1.000 to 2.000 inches, each conductor
2 conductors per phase—0.707 to 1.414 inches, each conductor
3 conductors per phase—0.577 to 1.155 inches, each conductor
4 conductors per phase—0.500 to 1 000 inches, each conductor

Conclusions

1. (*a*) Total cross-sectional conductor area per phase (based on outside diameter of each conductor) has the greatest effect on conductor surface voltage gradient; the greater the total area, the smaller the voltage gradient

(*b*) If the total conductor areas per phase are kept constant, the most judicious combination of the variables studied, results in a maximum decrease in surface voltage gradient of about 20 per cent of grouped conductors over the equivalent single conductor.

2. Appreciable reduction in surface volt-

Paper 48-285, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted August 3, 1948; made available for printing September 15, 1948.

M. Temoshok is with the central station engineering divisions of the General Electric Company, Schenectady, N. Y.

The author wishes to acknowledge the aid in calculating given by Miss M. D. Grems and Mrs. Doris Frost.

Figure 1. Flux and equipotential lines of center phase group of conductors

Intragroup spacing, 18 inches
Height above ground, 66.7 feet
Spacing between phases, 32 feet
A—1 conductor per phase, 2.00 inches in diameter
B—2 conductors per phase, each 1.414 inches in diameter
C—3 conductors per phase, each 1.155 inches in diameter
D—4 conductors per phase, each 1.000 inch in diameter

age gradients results with the following:

(*a*) Greater number of conductors per phase, up to an intragroup conductor spacing of approximately 25 inches.

(*b*) Smaller intragroup conductor spacing down to approximately 8 inches, below which the gradient increases.

(*c*) Greater spacing between phases.

3. Negligible effects on surface voltage gradients result with the following:

(*a*) Ground wires of practical installation.

(*b*) Height of conductors above ground of practical installation.

4. (*a*) For a horizontal configuration of the three phase groups of conductors, the maximum voltage gradient is on the center phase group of conductors.

(*b*) For this maximum conductor surface voltage gradient calculation, the effects of the other two phases are small and effectively cancel each other, and can therefore be ignored.

5. The greatest reduction in inductance and increase in capacitance is with increasing number of conductors per phase. Other factors producing this variation to a lesser degree are:

(*a*) Larger intragroup conductor spacing.

(*b*) Smaller spacing between phases.

(*c*) Greater total conductor area per phase.

6. A correlation between calculated conductor surface voltage gradients and corona loss can be accomplished with a co-ordinated test program.

Discussion of Results

Conductor Surface Voltage Gradients

The analytical method used in the calculation of conductor surface gradients is outlined in the Appendix. Since at the beginning of the study it was not known what assumptions could be made, an exact analytical approach was made and calculations performed with the aid of punched card computing machines with resulting accuracy of about 1 part in 5,000. It was possible to establish approximate methods and equations which resulted in accuracies in the final value of voltage gradients to within less than one per cent of the exact value.

A good physical picture of the phenomenon associated with flux conditions in a group of conductors at the same potential is necessary for understanding the effects of grouped conductors. Figure 1 illustrates the lines of force and equipotential lines for 1, 2, 3, and 4 conductors per phase of the center phase group of the three phase line. Configurations A, B, C, and D of Figure 3 indicate the charge distribution among conductors at the instant of time when the voltage on the center phase is +1, and that of the end phases −0.5. No ground wires were applied to these groups. Configurations E_1 and E_2 indicate the effect of ground wires, for a configuration slightly different from that of configuration B. Study of Figure 3 in conjunction with Figure 1 indicates the charge distribution among the conductors and the resulting lines of force emanating from the conductors of the center phase. Between conductors the lines of force are distorted, resulting in a variable voltage gradient around the conductor periphery. As the number of conductors increases, the charge per conductor decreases resulting in fewer lines of force. The smaller flux emanates from conductors of

decreasing circumference, resulting in a surface voltage gradient that tends to remain constant.

Initiation of corona and corona loss is contingent on the voltage gradients at the surface of the conductor. For a smooth, round, single conductor, with spacings from other conductors and above ground as in practical transmission line applications, the voltage gradient is approximately uniform around the periphery of the conductor. The corona calculations can be based on this single value. In grouped conductors a different problem evolves. The voltage gradient is not uniform around the conductor periphery, as is evident in studying Figures 1 and 2, and a correlation must be established between corona loss and the variable voltage gradient. Although in theoretical calculations, relative losses can be determined by working with, for example, the maximum conductor surface voltage gradient, only actual tests can establish the relationship between corona loss and the voltage gradients. After test investigations in France,[2] a criterion has been established for the two conductors per phase grouping, wherein the mean value of the maximum and average voltage gradients is used. Whether this relationship applies to three and more conductors per phase is to be determined. In this paper, only the maximum voltage gradients are studied.

Effect of Number of Conductors and Intragroup Conductor Spacing. Although, in general, the surface voltage gradients are smaller for grouped conductors than for single conductors, it is possible to attain a surface gradient with grouped conductors that is higher than the gradient with a single conductor of equal area. Increasing the intragroup conductor spacing to approximately 25 inches or more will produce this result. Figures 4(A), 4(B), and 4(C) illustrate that the greatest reduction in maximum voltage gradient is with conductors per phase of a greater number, and that a peak results with an intragroup conductor spacing of under 12 inches. It should be noted that the point of maximum per cent reduction of voltage gradient based on the single conductor value is analogous to the point of minimum voltage gradient. This minimum point of the maximum voltage gradient does not exist at only one intragroup conductor spacing, but varies according to the other parameters of the system.

With parameters determined by an average higher voltage transmission line, the maximum voltage gradient decreases with respect to the single conductor value. For example, at a 15-inch intragroup conductor spacing, the voltage gradient decrease for the grouped conductors is approximately 3 per cent, 9 per cent, and 14 per cent for 2, 3, or 4 conductors per phase, respectively. If intragroup conductor spacing is increased to 24 inches and more, not more than about 10 per cent maximum can be realized with any grouping of conductors up to four in number. If the spacing is further increased, the grouped conductor proximity effect on charge and flux is diminished and on sufficient separation vanishes entirely.

Figure 4. Surface voltage gradient reduction of grouped conductors based on value of single conductor of equivalent area

Spacing between phases, 32 feet
Height above ground, 66.7 feet

Intragroup conductor spacing is contingent on several major conditions: effect on conductor voltage gradient; effect on inductance and capacitance; striking and sticking of conductors due to wind; striking and sticking of conductors due to faults on the system; bridging of

conductors due to icing. Theoretical and practical investigations on the latter three conditions have recommended a minimum conductor spacing of approximately 15 inches.[1,2,3,4] It is possible though, where icing is not a major problem, to utilize a shorter conductor spacing, at the expense of more intragroup conductor spacers, if the first two conditions contribute sufficient benefits. The spacers tend to keep a uniform intragroup conductor spacing between line towers on normal load, and to keep conductors from striking due to attractive forces between conductors with the abnormally high current flow of certain fault conditions.

Effect of Spacing Between Phases. For the case of a single conductor of Figure 5, the conductor surface voltage gradient decreases about 10 per cent due to the increase of spacing between phases from 22 to 45 feet. Based on the single conductor value of voltage gradient at each particular spacing, the greatest reduction in voltage gradient is with the grouping of four conductors per phase and at the phase spacing of 45 feet. If the 45-foot spacing between phases is determined by insulation levels, a reduction of surface voltage gradient of 15 per cent is possible with the use of a 4-conductor grouping instead of the single conductor, at an 18-inch intragroup conductor spacing.

Effect of Conductor Diameter. With equal area per phase, there is practically a constant relationship between the surface voltage gradients of each group of the grouped conductors and the single conductor over the range of areas from 1.0 $\times 10^6$ to 4.0×10^6 circular mils. For the cases illustrated in Figure 6, the total decrease of voltage gradient in each of the four cases is about 44 per cent. Therefore for ease in calculation of gradients where change of area effects are required, the grouped conductors of any number, can be converted to an equivalent single conductor and the percentage change calculated.

Figure 6 best illustrates the gain in lower voltage gradients commonly attributed to grouped conductors. If all conductor diameters are 1.00 inch, the decreases due to 2, 3, and 4 conductors are 27.0, 42.6, and 51.0 per cent, respectively. To attain the same percentage decreases due to grouped conductors the single conductor diameter must be increased to 1.45, 2.00, and 2.32 inches, respectively.

Effect of Height Above Ground. Over the range, 25 feet to 70 feet, of the average height of conductors above ground, the variation in maximum surface voltage gradient is slightly over 1 per cent as expressed by Figure 7(A). As the height decreases, the effect of ground becomes more pronounced and the gradient increases. The relationship of voltage gradients between each group of the grouped conductors and the equivalent single conductor is practically constant over the entire range.

Effect of Ground Wires. Figures 7(A) and 7(B) indicate the small effect of ground wires. The range of ground wire location covers protective angles from 90 degrees (ground wire in line with conductors) to a protective angle of 31.3 degrees. If the protective angle is made smaller than 31.3 degrees, the gradient effect on the line conductors becomes almost negligible, under one-half per cent. For the usual protective angles the ground

wires will cause an increase in voltage gradient of less than 2 per cent at the line conductor surface. Although Figures 7(A) and 7(B) depict the two group conductor, the same relationships apply to the three and four group conductors.

Figure 3(B), configurations E_1 and E_3, illustrates the charge on the ground wires and the effect of the presence of ground wires in increasing the charge slightly on the center phase line conductors.

Effect of Configuration and Instantaneous Voltage Values. On a horizontal configuration of three phases, the middle phase will inherently have the higher charge, and also the higher surface gradient. This difference is approximately 5 to 10 per cent for the range of parameters covered in the study. The greater number of conductors per phase, with larger spacing between phases, tends toward the greater difference.

For single-conductor 3-phase lines with horizontal configuration, the maximum voltage gradient of all three phases exists on the middle conductor when the peak voltage on that conductor is slightly less than unity. The same applies to the 2-conductor grouping. When the center phase voltage has progressed 3 to 5 degrees in time from its maximum peak value, the surface gradient is the maximum. Figure 8 indicates that the maximum value differs so little from the value determined when the voltage on the center phase is unity, that for practical purposes the voltage distribution can be +1.0 for the center phase and −0.5 for the end phases for the maximum gradient calculation. Since the 2-conductor case error for this assumption was so negligible, checking the single conductor error, the 3- and 4-conductor cases were not investigated.

Inductive Reactance, Capacitive Susceptance, and Surge Impedance

In a previous article,[6] complete curves were presented for inductive reactance of grouped conductors up to five per phase and capacitive susceptance up to two, for certain ranges of intragroup conductor spacing, spacing between phases, and conductor diameters. This paper extends the earlier work to conductors and lines suitable for higher voltages. Surge impedance, $\sqrt{L/C}$ is introduced to give a clearer conception of the total effect of grouped conductors on inductance and capacitance. In the calculations of inductance, the internal construction of the conductor was not considered. Calculations were based on the assumption of smooth, solid, copper conductors.

A sense of proportion as to the effect of change in inductance and capacitance is attained by study of Figure 10. Throughout the range of variation in spacing of phases and number of conductors per phase, an interesting phenomenon occurs. The per cent variation of inductive reactance, and surge impedance of the grouped conductors based on the single conductor values, is almost identical, so that per cent decrease of inductance can practically be used as the per cent decrease of surge impedance. This is due to the relationship between inductance and capacitance where approximately

$$\frac{1}{1 + \text{per unit change in capacitance}} = 1 - \text{per unit}$$

change in inductance. The per cent increase in capacitive susceptance therefore is appreciably greater than the corresponding decrease in inductive reactance due to parameter changes.

Figures 9(A) and 9(B) indicate the variation of inductive reactance and capacitive susceptance with number of grouped conductors. As the number of conductors per phase increases, the rate of change of inductive reactance and capacitive susceptance decreases.

As intragroup conductor spacing increases, capacitive susceptance increases, and inductive reactance decreases as indicated by Figures 11(A) and 11(B). This desirable trend is compensated by the increase of surface voltage gradients as intragroup conductor spacing increases, and intragroup conductor spacing may actually be limited by the higher voltage gradients if the spacing increases appreciably beyond 25 inches.

For the single conductor diameter change from one to two inches, a decrease results in inductive reactance of almost 10

per cent for a 32-foot spacing between phases. As the number of conductors per phase increases, the effect of conductor area decreases, as indicated by Figure 12. For the 4-conductor grouping, the one to four change in phase area, results in a decrease in inductive reactance of only 4 per cent.

Appendix

For a 3-phase system with two conductors per phase the equations for the calculations of charges with certain applied voltages to ground are as follows:

$$V_1 = P_{11}Q_1 + P_{12}Q_2 + P_{13}Q_3 + P_{14}Q_4 + P_{15}Q_5 + P_{16}Q_6$$

$$V_2 = P_{21}Q_1 + P_{22}Q_2 + P_{23}Q_3 + P_{24}Q_4 + P_{25}Q_5 + P_{26}Q_6$$

$$V_3 = P_{31}Q_1 + P_{32}Q_2 + P_{33}Q_3 + P_{34}Q_4 + P_{35}Q_5 + P_{36}Q_6$$

$$V_4 = P_{41}Q_1 + P_{42}Q_2 + P_{43}Q_3 + P_{44}Q_4 + P_{45}Q_5 + P_{46}Q_6$$

$$V_5 = P_{51}Q_1 + P_{52}Q_2 + P_{53}Q_3 + P_{54}Q_4 + P_{55}Q_5 + P_{56}Q_6$$

$$V_6 = P_{61}Q_1 + P_{62}Q_2 + P_{63}Q_3 + P_{64}Q_4 + P_{65}Q_5 + P_{66}Q_6$$

where

$V_1 = V_2$
$V_3 = V_5$
$V_5 = V_6$

$$P_{11} = P_{22} = P_{33} = P_{44} = P_{55} = P_{66} = 2 \log_e \frac{2h}{r}$$

$$P_{jk} = P_{kj} = 2 \log_e \frac{S_{jk}}{s_{jk}}$$

S_{jk} = distance between centers of the jth conductor and the image of the kth conductor

s_{jk} = distance between centers of the jth and kth conductors

Since the configuration of the transmission line is known, all values of P's can be calculated, assigned, leaving values of Q, charge, to be solved.

Inclusion of ground wires, and cases of three, or four conductors per phase, extends the number of terms and equations. The case of two ground wires, with four conductors per phase, results in 14 equations of 14 terms each.

As it was not known at the beginning of the study what assumptions and simplifications could be made in the solution for the charges, the Matrix Method[7] was selected, as this method introduces the inverse matrix and lends the greatest flexibility in the general solution of the problem, wherein the applied voltages to the phases were varied.

As the total number of cases to be studied was large, and the number of simultaneous equations was 6 to 14, the amount of work was almost prohibitive with the usual mathematical aids. The punched card calculators were applied admirably to the problem, with a maximum error of less than 0.02 per cent. Results indicated in Figure 3 and Figure 8 were derived, indicating the possible use of approximate methods with practically accurate results. Having discovered that the conductors of the middle phase group have the highest gradient when practically speaking, the voltage is unity on that phase, considerable simplification was possible. Symmetry of the end phases with the center phase exists, so that the six equations for two conductors per phase case with no ground wires, reduce to three; the nine equations for the three conductors per phase reduce to five; and the twelve equations for the four conductors per phase reduce to six. The maximum number of equations is seven for the case of four conductors per phase and two ground wires.

Since the voltages to be applied to the lines, for the symmetrical, simplified cases, are not varied but remain constant, the Matrix Method for these cases loses its virtue and a method such as the Method Based on Elimination[7] best lends itself to the solution of the desired charges.

The complete equation for the field intensity at a conductor due to other conductors, after the solution for the line charges has been made, is

$$E_1 = 2\sqrt{\left[\sum \frac{1}{m_{1n}} \cos \theta_{1n} Q_n + \sum \frac{1}{S_{1n}} \cos \theta_{1n} Q_n\right]^2 + \left[\sum \frac{1}{m_{1n}} \sin \theta_{1n} Q_n + \sum \frac{1}{S_{1n}} \sin \theta_{1n} Q_n\right]^2} \quad (1)$$

m_{1n} = distance between conductor 1 and all other conductors in the same phase group

S_{1n} = distance between conductor 1 and all other conductors of other phase groups including ground wires

θ_{1n} = angle between conductor 1 and all other conductors, including ground wires

Q_n = charge on all conductors except 1

Since the contributions to the field intensity of the conductors of the other two phases than the one in question, are usually under 0.5 per cent, ignoring these effects results in the simplified equation.[8]

$$E_1 = 2\sqrt{\left[\sum \frac{1}{m_{1n}} \cos \theta_{1n} Q_n\right]^2 + \left[\sum \frac{1}{m_{1n}} \sin \theta_{1n} Q_n\right]^2} \quad (1a)$$

The maximum field intensity at a conductor becomes:

$$E_{m1} = 2E_1 + \frac{2Q_1}{r_1} \quad (2)$$

where

Q_1 = charge on conductor 1
r_1 = radius of conductor 1

Equations 1 and 1a are accurate to intragroup conductor spacings as low as 8 inches for most cases. For intragroup conductor spacings such that

$$\frac{\text{intragroup conductor spacing}}{\text{conductor diameter}} < 6,$$

at least one per cent and up to 25 per cent error may result, so that an analytical approach is necessary to account for the field produced by other conductors not being uniform in the region of the conductor considered. Hillel Poritsky made an investigation of the 2-conductor case in 1932.[9]

For the number of conductors and configurations of the subject study, the equations for the maximum surface gradients become with good approximation:

$$\text{2 conductors } E_{m1} = \frac{4Q}{d} + \frac{4Q}{m} \tag{3a}$$

$$\text{3 conductors } E_{m1} = \frac{4Q}{d} + \frac{6.9284}{m} Q \tag{3b}$$

$$\text{4 conductors } E_{m1} = \frac{4Q}{d} + \frac{8.484}{m} Q \tag{3c}$$

d = diameter of conductor, inches
Q = average maximum charge among conductors in the phase
m = intragroup conductor spacing

The inductance to neutral per conductor is[8]

$$L_c = 0.08047 + 0.74113 \log_{10} \frac{24(S_{gm})^n}{d(m_{gm})^{n-1}} \quad \text{millihenrys per mile} \tag{4a}$$

Inductance per phase

$$L_\phi = \frac{L_c}{n} \tag{4b}$$

The capacitance to neutral per conductor is[8]

$$C_c = \frac{0.03883}{\log_{10} \dfrac{24(S_{gm})^n}{d(m_{gm})^{n-1}}} \quad \text{microfarads per mile} \tag{5a}$$

Capacitance per phase

$$C_\phi = nC_c \tag{5b}$$

where:

S_{gm} = geometric mean distance between conductors of different phases, feet
m_{gm} = geometric mean distance between conductors of the same phase, feet
n = number of conductors per phase
d = diameter of conductor, inches

Discussion

W. A. Lewis (Illinois Institute of Technology, Chicago, Ill.): The paper by Temoshok is an interesting development of surface gradients in the neighborhood of grouped conductors which have been suggested for power transmission at higher voltages than those now in use in the United States. All of the developments, however, are based on the assumption that each of the conductors has a smooth outer surface. With the exception of the Hoover Dam line, a very large majority of the high-voltage lines now in use in the United States make use of stranded conductors, rather than the smooth conductors referred to in the paper. Although the type *HH* design approximates quite closely the smooth conductor, it is quite probable that stranded conductors may also be given serious consideration for the higher voltages, when grouped conductors are considered. To make the work of the paper of maximum usefulness, therefore, it is desirable to see what can be done to extend the analysis to the case of stranded conductors.

A fairly satisfactory first approximation of this result can be obtained in the following manner. Let us consider first a single conductor of a length very long in comparison with the spacing between the conductor considered and the other conductors of the circuit. If the spacing between conductors is quite large in comparison with the conductor radius, the voltage gradient at the surface of the conductor will be very nearly the same as for a single conductor with the return a concentric cylinder at a large distance. For the latter case, the surface gradient will be uniform all the way around the conductor, and can be calculated by determining the gradient due to a uniform line charge located at the center of the conductor.

For a stranded conductor, it may be assumed that the charge of the conductor, instead of being concentrated along a line at the center of the conductor, is divided into n equal parts where n is the number of strands in the outer layer of the conductor. If these n charges are distributed symmetrically about the center of the conductor at a radial distance from the center somewhat less than the radius of the circumscribing circle, it is possible to calculate the equipotential surfaces which result. By a little manipulation, it is readily possible to locate these charges at a distance from the center which will cause one of the equipotential surfaces to coincide very closely with the outer surface of the strands where the strands protrude. In the grooves between the strands, the calculated equipotential surface does not agree closely with the conductor outline, but in this region the gradient is much less, so that a high degree of accuracy is not necessary for the calculation of the maximum gradients.

Although this analysis will not apply rigorously for the case of grouped conductors, it will provide an approximate basis for determining the effect of stranding.

An analysis of this kind indicates that the maximum gradient at the surface of one of the strands is approximately 37 per cent greater than the average gradient at the surface of a smooth cylinder of the same outside radius. If the corona starting voltage and corona loss for both a stranded conductor and a smooth conductor are dependent only on the maximum gradient at any single point at the surface of the conductor, this analysis would indicate that corona would start for a stranded conductor at a voltage approximately 73 per cent of that for a smooth conductor. The test results available indicate that the corona loss for a stranded conductor is greater than that for a smooth conductor of the same radius, but the difference is by no means as great as that indicated by comparison of the maximum gradients.

It is therefore reasonable to conclude that the corona loss is not dependent on the maximum gradient only, but is a function of the manner in which the gradient varies from point to point around the surface of the conductor when the gradient is variable. As a first approximation, it might be assumed that the corona loss depended upon the average gradient at the surface of the conductor, the average being obtained as the mean of the maximum and minimum voltage gradients. With the method of calculation described, the minimum gradient is not obtained as accurately as the maximum gradi-

ent, but the average of the two might form a basis for analyzing corona-loss data. On this basis, the average gradient at the surface of a stranded conductor is given approximately by equation 1 as follows:

$$g_1 = \frac{1.07\, e_1}{r_n\left[\log_e \frac{d_{12}}{r_n} + \frac{0.136}{n}\right]} \quad \text{(average gradient)} \qquad (1)$$

where

e_1 = line-to-neutral voltage, kilovolts
g_1 = gradient, kilovolts per foot
n = number of strands in outer layer
r_n = radius of conductor circumscribing circle, feet
d_{12} = geometric mean distance to return conductor, feet

For a smooth conductor the gradient, both average and maximum, is given by equation 2 as follows:

$$g_1 = \frac{e_1}{r \log_e \frac{d_{12}}{r}} \quad \text{(uniform gradient)} \qquad (2)$$

where

r = radius of conductor, feet

When n is 12 or more, n being the number of strands in the outer layer of the stranded conductor, the average gradient at the surface of the stranded conductor is approximately seven per cent greater than it is for a smooth conductor of the same radius. Thus, the corona loss for a stranded conductor is approximately the same as that for a smooth conductor if the voltage is increased seven per cent. Such a figure is more nearly in agreement with the available test data than is the 37 per cent difference in voltage based upon the maximum gradient.

As a basis for further study, it may therefore be suggested that the method proposed could be used to include approximately the effect of stranding in analytic calculations of this type.

C. F. Wagner (Westinghouse Electric Corporation, East Pittsburgh, Pa.): While Temoshok had apparently not intended that his references be exhaustive of the subject, I would like to call attention to some of the earlier work done in Europe on bundle conductors. I refer, first, to the work of Markt and Mengele in Austria that was reported in *Elektrotechnik und Maschinenbau* in 1932 and 1938; and, second, to the Siemens-Schuckertwerke investigations. The work by Siemens-Schuckertwerke constitutes the most comprehensive studies on this subject and includes corona aspects, inductance and capacitance values, ice loading, and stringing methods. These investigations were reported by the Siemens-Schuckertwerke under the title "Bundelleitungen" in 1942, and were under the authorship of Mangoldt, Busemann, Burklin, Markt, and Kroner, and became available in America shortly after the cessation of hostilities.

Temoshok has stressed the maximum potential gradient and uses this as a criterion to compare different configurations of conductors. If this is the only quantity he was seeking, it could have been obtained in a somewhat simpler manner. While the method the author uses is beyond criticism from the standpoint of accuracy, much of the physical significance of the phenomenon is lost by this approach. Calculations made on a 2-inch diameter single-conductor 3-phase line of flat configuration in which the spacing was 45 feet between conductors, the conductors 70 feet above ground and with two ground wires 40 feet above the conductors and midway between them, showed that the potential gradient at the middle conductor was four per cent above the mean and the two outside conductors was two per cent below the mean. This example is merely cited to illustrate the more general and well-known fact that the gradient of the center conductor is the largest of the three. If one is concerned with maximum gradients only, detailed consideration need be given to the middle conductor only.

If it were assumed that the charges on all conductors comprising the center phase were equal, great simplification results. This assumption is rigorously true for a 2-conductor group in horizontal configuration, and can be shown by simple calculation to be correct within a small fraction of one per cent for most practical configurations. This is borne out by diagrams in Figure 3 which show, for example, that the charges on the 4-conductor group are equal to within about 0.1 of one per cent.

The comparisons made by Temoshok have all been made on the basis of maximum gradient, but he points out in referring to the work done in France that only tests can establish the relation between corona loss and voltage gradient. Since the voltage gradients on the three phases for flat configuration are not equal, the losses on the respective phases will likewise not be equal. The total loss on a line can probably be determined by using as a base the calculated gradients on each of the conductors and summing up the losses of all conductors. In view of this complication, it is likely that a good over-all compromise for practical calculation purposes might be obtained by assuming the phases located at the points of an equilateral triangle for which the spacing is equal to the geometric mean of the actual spacings, by neglecting the presence of ground and ground wires, and by assuming in addition that the charges on all conductors are equal. The maximum gradient obtained under these conditions might then be used as the criterion to compare performance or to compute the critical breakdown voltage. With these assumptions, the calculations become relatively simple.

For a perfectly smooth polished conductor for which there is only one per phase, according to Peek[10] the disruptive critical voltage to neutral (crest value) is

$$e = g_o r \log_e \frac{D}{r} \text{ in kilovolts to neutral} \qquad (1)$$

where

g_o = critical gradient, which Peek took as 30 kv per centimeter
r = radius of conductor
D = distance between conductors

If each phase consists of a 2-conductor group of spacing, S, separated a distance, D, the critical disruptive voltage is

$$e = g_o \frac{2}{1+2\frac{r}{s}}\, r \log_e \frac{D}{\sqrt{rs}} \qquad (2)$$

If each phase consists of a 3-conductor group

$$e = g_o \frac{3}{1+3.464\frac{r}{s}}\, r \log_e \frac{D}{3\sqrt[3]{rs^2}} \qquad (3)$$

If each phase consists of a 4-conductor group

$$e = g_o \frac{4}{1+4.242\frac{r}{s}}\, r \log_e \frac{D}{1.189^4\sqrt{rs^4}} \qquad (4)$$

If each phase consists of a 6-conductor group

$$e = g_o \frac{6}{1+5.310\frac{r}{s}}\, r \log_e \frac{D}{1.348^6\sqrt[3]{rs^4}} \qquad (5)$$

Each of the foregoing expressions is of the following form:

$$e = g_o \frac{n}{1+A}\, r \log_e \frac{D}{r_{eq}} \qquad (6)$$

The denominator in the logarithmic term, r_{eq}, is merely the geometric mean radius of the group. Thus the reciprocal of the logarithmic term is proportional to the capacity and to the total charge per group. Note that the n term is the number of conductors per group, and is present because it converts the total charge to the charge per conductor. In other words, the combination of the n term and the logarithmic term merely reflects the charge per conductor. The gradient around the periphery of the conductor due to the charge on itself is uniform. "A" expresses the influence of the charges on the other conductors comprising a group. Thus upon drawing a line through one of the conductors to the center of the group, the gradient along this line on the outward side is increased A per unit, and on the inside is decreased A per unit. Between these two extremes the gradient varies in a cosinusoidal manner around the periphery of the conductor.

In Peek's work he indicated that g_o is constant for conductors of diameters that would be used for high-voltage transmission. Peek's data and that of subsequent investigators raises considerable doubt as to whether g_o is constant in the range of low losses in which the transmission engineer is concerned. The indications are that g_o might well increase with decreasing radius. If that be so, this factor should be taken into consideration and would be regarded as a factor favorable to bundle conductors.

For visual corona, g, according to Peek is

$$g_v = 30\left(1+\frac{0.301}{\sqrt{r}}\right) \qquad (7)$$

The critical visual voltage, in kv to neutral, is then for say a 4-conductor group

$$e_v = 30\left(1+\frac{0.301}{\sqrt{r}}\right)\frac{4}{1+4.242\frac{r}{s}} \times r \log \frac{D}{1.189^4\sqrt{rs^4}} \qquad (8)$$

Most of Temoshok's comparisons are based upon equal cross-sectional areas of conductors of solid section. In the realm of

transmission voltages for which bundle conductors would be considered, both the conductors comprising the bundle and the competitive single conductors would not be of this construction. I refer to such conductors as the expanded ACSR (aluminum cable, steel reinforced), the sectored conductor commonly known as *HH*, and the I-beam conductor. The data can be converted to a radius basis, but with some inconvenience to the reader.

M. Temoshok (General Electric Company Schenectady, N. Y.): The results of Lewis in analyzing the effect of stranding on the conductor surface voltage gradients checks the results of W. S. Peterson[1] where the number of conductors is greater than 12. Another approach is the use of the grouped conductor method of flux plots as presented in the paper. This method of flux plots is similar to Lewis' analytical approach. In this case the conductors are grouped with a circular disposition and spaced one diameter apart between conductor centers. This flux plot result checks the maximum gradient value of 37 per cent greater than that of the smooth conductor, as derived by Lewis and by use of Peterson's equation.

One major purpose of the paper was to present relative gradients of grouped conductors compared with single. Similar relationships would have resulted had stranded conductors been considered instead of smooth, but with much greater complexity in their derivation. The stranding effects are important and Lewis' contribution has merit where absolute values of gradients are required.

A practical approach to introduce the stranding effect into corona loss equations is to calculate gradients for conductors as if they were smooth, then introduce a stranding factor. A factor of 0.92 was suggested by Peterson[1] for a well-weathered stranded conductor. This would check very closely Lewis' factor of 7 per cent, as putting the factors on a common base the reciprocal, 1/1.07, would be used.

Corona loss is known to exist at a voltage well below that value at which the gradient at the conductor surface is equivalent to the breakdown gradient of air, 53.6 kv effective, per inch. This loss is due to surface conditions, such as roughness or irregularities, of the conductor, resulting in corona loss known as brush loss. Likewise, corona loss may begin to exist at low voltages due the high surface gradients at each strand, but that these losses may not follow a well-defined pattern, until the higher voltages are reached where the corona losses begin to fit into fairly well defined patterns as suggested by Peterson and Peek.[1,2] A mean gradient determines the actual loss for single stranded conductors in the same manner apparently as that found by Cahen[3] for grouped conductors, and which was discussed in the main paper. The corona loss did not vary according to the maximum surface gradient of the dual conductors, but according to the mean gradient of the maximum and the average.

As Wagner pointed out it is a known fact, or it can be easily indicated, that the maximum surface gradient of the center conductor is the highest of three single conductors in a horizontal configuration. Whether a perfectly analogous situation existed with grouped conductors and what relationship existed between the maximum surface gradients among phases and among conductors of a group was one problem of this study. This could only be accomplished by an exact approach, and from which future approximations could be justified.

Wagner's method, of simplifying conditions for corona calculations by placing conductors at the points of an equilateral triangle and assuming equal charges on all conductors, has merit. But the actual mean maximum charge on the end conductors can differ from the mean maximum charge on the center conductors by approximately 10 per cent for the three or four conductors per phase groupings, and among the conductors of the end groups approximately a 5 per cent variation in charges among the individual conductors may exist. As these variations differ materially from those of the one and two conductor groupings, one equivalent representation of all groupings may not be sufficiently accurate.

There is evidence in test data that an apparent increase in g_o exists with decreasing radius. If test corona losses are plotted as functions of the conductor surface gradients, and referring all other parameters to a common base, there is a tendency for smaller conductors to have smaller losses. As stated by Wagner, this would indicate lower losses for grouped conductors compared with losses of the equivalent single conductor.

The objection of Wagner to the use of total cross-sectional area of conductors per phase as a basis of comparisons among grouped and single conductors, is not apparent. This method is flexible and can be used to compare any types of conductors and any number of conductors per phase. If resistance values or material weight enter as criterions, different values of area may result for each grouping, but the same reference base can be used. In fact the comparisons where actual diameters are used are the ones to heed, unless the assumption is made, as in the paper, that comparisons are made between conductors of the same kind.

Mercury-Arc Frequency Converter for Induction Heating of Metals

S. R. DURAND
MEMBER AIEE

J. B. RICE
MEMBER AIEE

Synopsis: An analysis is presented of the theory of operation of mercury-arc equipment for converting 3-phase power of commercial system frequencies into single-phase power of a frequency of the order of one kc for use in induction heating and melting applications. Mathematical relationships are derived to show the effect of both low- and high-frequency commutation and the frequency response of the grid phase angle control on the high-frequency output voltage and regulation. The self-tuning characteristics of the circuit are analyzed and a comparison is made between its response and that of a motor-generator set to changes in the load circuit inductance. Some practical considerations are discussed in connection with the installation and operation of mercury-arc frequency changing equipment of several hundred kilowatts rating for induction melting service.

INDUCTION melting of high-grade alloys has been accomplished in the United States during the past 25 years by converting 60-cycle electric power into a frequency of 960 cycles, in general, by means of motor-generator sets. Within the last few years, a static-type frequency changer has been developed to obtain electric power at a frequency of the order of one kc for induction heating and melting applications.[5,12] An analysis of the circuit theory and performance characteristics of this electronic frequency conversion equipment has been of importance in connection with the design of equipment of several hundred kilowatts rating for installations in industrial plants and foundries.

Operation Viewed as a Steady-State Phenomenon

The basic circuit used at the present time to obtain single-phase kilocycle frequency power from a 3-phase 60-cycle network is shown in Figure 1. The 60-cycle transformer is a 3-phase rectifier transformer with a zigzag secondary winding. The high-frequency transformer is a 4-winding single-phase transformer designed for operation at the output frequency usually of the order of 1,000 cycles. The three primary windings of this transformer are connected to the anodes of a mercury-arc converter unit. This converter unit is of a type well known in the transportation, electrochemical, steel, and mining industries, where it is used extensively for rectifying a-c into d-c electric power. A reactor is included in the circuit for interconnecting the mercury pool cathode of the converter unit with the neutral terminal of the zigzag winding of the 60-cycle transformer. The output winding of the kilocycle-frequency transformer is connected to the induction heating coil and capacitor circuit.

Essentially, the basic circuit consists of a 3-phase single-way rectifier, which converts power from the 60-cycle network into direct current, and a single-phase inverter,[1,6] which converts direct current into power at a frequency desired for the induction heating application. The inverter operates into a tuned circuit consisting of the inductance of the heating coil and capacitance of a bank of capacitors in parallel with the coil. Voltage for control of the mercury-arc converter grids is obtained from the tuned output circuit and thus is fed back in a somewhat similar manner to that employed in the well-known tuned plate oscillator.

Assuming that the circuit is operating under steady-state conditions, the voltages e_{a1} and e_{a2} from the center tap of one of the high-frequency transformer windings to anodes 1 and 2 may be shown as in Figure 2. Also assume that during the time illustrated in Figure 2, phase A of the 60-cycle zigzag transformer winding is more positive than either phase B or C, and that at time t_0 to t_1, anode 2 alone is carrying current. Neglecting arc drop, the cathode of the mercury-arc converter unit is thus at the same potential as anode 2 in this time. Anodes 4 and 6 will be negative with respect to the cathode because, neglecting the impedance drop in the transformer windings, they have the same high-frequency voltage as anode 2 but less positive 60-cycle potentials. Anodes 3 and 5, which have the same high-frequency voltages as anode 1, are similarly less positive than anode 1 because they also have less positive 60-cycle potentials.

It is convenient with this circuit to ground the cathode, and, from an analytical standpoint, to consider the cathode as being always at zero potential. Thus, the cathode potential may be drawn as the zero line of Figure 3, and the voltage of anode 1 to cathode e_{k1} is represented by the solid line. During the nonfiring period of anode 1 (while anode 2 is firing) this voltage is twice the anode-to-neutral voltage e_{a1} of the high-frequency transformer.

From t_0 to t_1, anode 2 is firing, and anode 1, even though it is more positive, is prevented from firing because a negative potential is maintained on its grid. At the instant t_1, anode 1 is released by permitting its grid to become positive, but because of the leakage inductance of the transformer, the current flowing to anode 2 cannot be instantly extinguished, so that from time t_1 to t_2 both anodes are carrying current and are effectively at cathode potential. This is called the overlapping period.

At instant t_2, commutation of the arc current from anode 2 to anode 1 is completed, and anode 2 stops carrying cur-

Paper 48-287, recommended by the AIEE electric heating and electronic power converter committees and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Figure 1. Circuit diagram of mercury-arc converter for induction heating

Figure 2. High-frequency transformer-primary voltage during firing period

rent. Anode 1 remains at cathode potential, and anode 2 assumes a value e_{13} equal to twice the phase-to-neutral voltage, e_{a1}. Anode 1 carries current until instant t_4 when anode 2 is again released by its grid, and commutation of the arc current from anode 1 back to anode 2 will take place.

Referring again to Figure 2, the shaded areas show the value of e_{a1} during the time between t_2 and t_4 that anode 1 is firing. At t_4, voltage, e_{a1}, changes from a positive to a negative value. Even though e_{a1} becomes larger in magnitude than the phase-to-neutral 60-cycle voltage, e_{t1} at some time during the firing period, the inductance of the cathode reactor is designed to be large enough to keep current flowing from anode 1 to the cathode. The fact that the average value of the voltage, e_{a1}, is negative during the firing period of anode 1, as may be seen from the relative magnitudes of the shaded areas, shows that power is being delivered to the load.

It is evident that during the overlapping period t_1 to t_2 which persists during the angle u, the voltage input to the high-frequency circuit is zero, so that even though anode 1 is released at t_1, the high-frequency voltage is not developed until time t_2 at an angle ϕ equal to $(\beta-u)$. The angle ϕ is termed the "margin" angle, and the corresponding time from t_2 to t_3 is designated the "margin time" or "available deionization time." In this time, anode 2, which has ceased firing, is at a negative potential, and its grid must gain blocking control through deionization of the space surrounding it so as to prevent re-ignition of the arc after time t_3 when the voltage on anode 2 becomes positive.

Assuming that the inductance of the cathode reactor is large enough not only to smooth out the high-frequency current but also to substantially eliminate the 180-cycle ripple from the 3-phase 60-cycle rectified output, the high-frequency voltage produced by inversion can be considered as derived from a smooth d-c voltage. If the transformer windings are considered to have negligible resistance and the cathode reactor is assumed to be a pure inductance, the average value of the high-frequency voltage during 1/2 cycle (π radians) must be equal to E_d. This follows from the fact that the average voltage across a perfect inductance must be zero.

The value of the high-frequency voltage may be determined by integrating the sine wave within the proper angular limits. Designating the maximum value of the high-frequency voltage by E_m, an expression for this voltage, as represented by the two parts of the shaded areas of Figure 2, may be written and equated to the d-c voltage as follows (see list of symbols in Appendix):

$$\frac{E_m}{\pi}\left(\int_0^{\pi-\beta} \sin\theta d\theta - \int_0^{\phi} \sin\theta d\theta\right) = E_d \tag{1}$$

Substituting

$$\cos(\pi-\beta) = -\cos\beta$$

and

$$\phi = \beta - u$$

$$\frac{E_m}{\pi}\left[(\cos\beta + \cos(\beta-u)\right] = E_d \tag{2}$$

$$E_m = \frac{\pi E_d}{\cos\beta + \cos(\beta-u)} \tag{3}$$

or the rms value of the high-frequency voltage is

$$E_{hf} = \frac{\pi}{\sqrt{2}} \frac{E_d}{\cos\beta + \cos(\beta-u)} \tag{4}$$

The overlapping angle u depends upon the transformer leakage impedance, the value of the cathode current, and the angle β (which determines the commutating voltage). The angle u, therefore, cannot be changed at will in operation. However, the magnitude of the output voltage may be varied within limits by controlling either the d-c voltage, E_d, or the angle of advance, β, and both methods are used. E_d can be raised or lowered by changing taps on the 60-cycle transformer, or it can be lowered by applying 60-cycle phase control to the grids. This method of phase control to regulate the part of the 60-cycle voltage wave over which the anodes fire and carry current is well known in connection with the appli-

Figure 3. Anode-to-cathode voltage wave shape

cation of mercury arc converters in rectifier service, and a wide range of smooth power control is possible in this manner.

Output voltage control by varying the angle of advance, β, is applicable over only a limited range. If β is decreased too much, the margin angle ϕ becomes so small that deionization time is insufficient, and the grids lose control. At small values of β, the commutating voltage also decreases, and so u increases, thus further shortening the value for a safe margin angle ϕ. On the other hand, it is apparent that the fundamental component of the output current leads the output voltage by the angle ϕ (neglecting the overlapping angle u), so that if the angle ϕ is increased, the output current becomes more leading. The power factor of the output is approximately cos ϕ. This places a limitation on the range of control available by increasing the angle of advance, β, and consequently increasing the value of ϕ, since increasing β too much may cause the kilovolt-ampere rating of the high-frequency transformer to become excessive for a given kilowatt output.

The fact that the output current leads the voltage by the angle ϕ results in the operating frequency adjusting itself to a value sufficiently above the resonant frequency of the load circuit so that the current will become leading by this amount. The frequency shift required to produce a given angle ϕ between the current and voltage depends upon the Q (quality) of the heating coil. The value of $Q(\omega L/R)$ for a typical induction furnace is about ten. As a rule, the operating-frequency will be about three per cent higher than the resonant frequency of the load.

The discussion of the theory of operation has been confined to the commutation of arc current during one cycle of the high-frequency output. Under actual operating conditions, current will be transferred several times between anodes 1 and 2, while phase A of the zigzag winding of the 60-cycle transformer is more positive than phases B and C. As each of these 60-cycle transformer phases becomes more positive in turn, anodes 1 and 2 will cease commutating the arc current between them, and anodes 3 and 4, and, later, 5 and 6 will take over successively. Since the three high-voltage windings of the single-phase transformer supplying these pairs of anodes is closely coupled to the low voltage winding, high-frequency power will be supplied continuously to the output circuit.

Figure 4 is a typical oscillogram showing (A), the anode-to-cathode voltage, (B), the grid-to-cathode voltage, (C), the anode current of one anode, (D), the output voltage, and (E), the output current. The alternate conducting periods of one anode of a pair is shown by oscillograph trace, (C), during the 60-cycle conducting period of its phase. It is apparent that the phase conducting period is about one-third of a 60-cycle period as marked on the oscillogram.

Operation Viewed as a Series of Transients[3,4]

In the foregoing, the high-frequency output voltage and current have been treated as steady-state phenomena. In reality, the output voltage is composed of a series of transients during the conducting periods which alternate with another series of transients during the commutating periods. Each conducting period transient may be thought of as being initiated by the sudden recovery of voltage across the primary of the high-frequency transformer at the instant commutation is completed. Each commutating period transient is initiated by the sudden short-circuiting of the transformer primary winding when the entering anode fires at the beginning of the commutating period.

Each conducting period voltage transient, e, is a portion of a damped sine wave, of the form

$$e = -E_m \epsilon^{-t/\tau} \sin(\omega t - \phi) \qquad (5)$$

where $\tau = 2L/R$ and L and R are the inductance and equivalent resistance respectively of the loaded inductor coil. Typical time constants, τ, encountered in practice are in the neighborhood of four milliseconds, while the firing period lasts less than 1/2 millisecond for 1,000-cycle operation. For these values, the damping factor, $\epsilon^{-t/\tau}$, at the end of each transient would be $\epsilon^{-1/8} = 0.88$. Although this damping is appreciable, the error introduced by assuming undamped sine waves in the previous analysis is negligible for two reasons. First, the average value given by that analysis is correct because it is based only on the assumption that the average high-frequency voltage equals the average direct voltage, and that is true for the actual damped wave. Second, it can be shown that the ratio of rms value to average value of a damped sine wave does not deviate appreciably from that of a true sine wave for the interval covered by each transient and the damping factors encountered. Therefore, it follows that the rms value of voltage calculated from equation 4 is sufficiently close to the actual rms voltage.

The high-frequency voltage during commutation is of the same form as the conduction transient, but the tuned load circuit is paralleled by the leakage impedance of the high-frequency transformer. This causes the frequency to increase and the time constant to decrease somewhat, but the duration of the commutation transient is so short (less than 1/10 millisecond) that the effect of damping is entirely negligible for practical considerations.

Voltage Regulation

The voltage regulation of the entire circuit during a normal melting cycle may be thought of as made up of three components: regulation of the direct voltage due to increase of the 60-cycle overlap with increasing load; equivalent IR drop in the direct voltage due to copper losses in the 60-cycle-transformer, cathode reactor, and high-frequency transformer; and regulation due to the increase of high-frequency overlap with increasing load. The converter arc voltage drop, which is relatively constant over the normal load range, theoretically also should be subtracted from the direct voltage, but because of operation at a relatively high voltage, the change in arc drop is less than 0.2 per cent and therefore can be neglected for calculation of regulation. Each component of regulation is analyzed separately, and an expression for the total voltage drop is derived.

Figure 4. Oscillogram of high-frequency voltages and currents

Figure 5. High-frequency commutation

The expression for voltage drop of the direct voltage of a three-phase single-way rectifier due to overlap is well known:

$$E_{x1}=\frac{I_d X_{c1}}{2\frac{\pi}{3}} \tag{6}$$

where X_{c1} is the commutating reactance of the 60-cycle rectifier transformer and I_d is the cathode current.

The resistance losses in all the transformer and reactor windings appear as a reduction in the direct voltage which is proportional to the cathode current and therefore can be represented by:

$$E_r=I_d r \tag{7}$$

$$r=\frac{P_r}{I_d^2} \tag{8}$$

where P_r is the total copper loss of all the windings.

The average direct voltage under load (neglecting arc drop) can now be expressed as follows:

$$E_d=E_{d0}-E_{x1}-E_r \tag{9}$$

$$E_d=E_{d0}-I_d\left(\frac{3}{2\pi}X_{c1}+r\right) \tag{10}$$

Where E_{d0} is the no-load direct voltage whose well-known expression is:

$$E_{d0}=\frac{3\sqrt{2}}{\pi}E_s\sin\frac{\pi}{3}=\frac{3\sqrt{3}}{\pi\sqrt{2}}E_s=1.17E_s \tag{11}$$

In order to determine the voltage drop due to high-frequency overlap, high-frequency commutation first must be analyzed. As previously explained in connection with Figure 3, during the commutation interval from t_1 to t_3, both anodes are carrying current which effectively constitutes an electrical connection between them. Since the voltage on the output winding of the transformer is sustained by the large capacitor bank, a short-circuit current will start to build up which will flow through the high-frequency primary windings and the two anode arcs in such a direction as to increase the current of anode 1 and decrease that of anode 2. When the current of anode 2 becomes zero and that of anode 1 becomes equal to I_d, commutation is completed. During this time, the transformer primary current in effect has changed from $-I_d$ to $+I_d$ since the ampere turns have changed from $-nI_d$ to $+nI_d$, n being the turns from one terminal to the center tap. The time required for commutation can therefore be regarded as the time for the short-circuit current in the primary (one terminal to the center tap) to build up to $2I_d$ This is illustrated in Figure 5. As shown, the commutating current, i_c, will be offset from zero to satisfy the condition that $i_c=-I_d$ at zero time (when anode 1 fires). The resistance of the windings is neglected so that the commutating current lags the secondary voltage by 90 degrees. From Figure 5, the following relations are evident:

$$a=I_{cm}\cos\beta \tag{12}$$

$$b=I_{cm}\cos(\beta-u) \tag{13}$$

I_{cm} is indicated on Figure 5.

$$b-a=2I_d=I_{cm}\Big[(\cos(\beta-u)-\cos\beta)\Big] \tag{14}$$

Therefore

$$\cos(\beta-u)-\cos\beta=2\frac{I_d}{I_{cm}} \tag{15}$$

$$\cos\beta+\cos(\beta-u)=2\left(\frac{I_d}{I_{cm}}+\cos\beta\right) \tag{16}$$

But

$$I_{cm}=\sqrt{2}\,I_c=\frac{\sqrt{2}E_M}{X_{c1}} \tag{17}$$

where X_{c1} is the commutating reactance of the high-frequency transformer in primary terms.

$$X_{c1}=\omega_c L_c \tag{18}$$

In computing X_{c1}, it must be remembered that the angular frequency, ω_c, during commutation is considerably greater than the natural angular frequency, ω, of the tuned circuit because the inductance of the heating coil is paralleled by the leakage inductance of the transformer, so that

$$\frac{\omega_c}{\omega}=\left(1+\frac{L}{L_c}\right)^{1/2} \tag{19}$$

In a typical case, the commutating inductance, L_c, is slightly less than the heating-coil inductance, L, so that the ratio of ω_c to ω is approximately $1^1/_2$. This increase in frequency during commutation causes a slight distortion in the voltage wave. However, the voltage is shown as a pure sine wave in Figure 5 and β is defined as the angle measured from the zero of this wave to the firing point.

Now, substituting equation 17 in 16:

$$\cos\beta+\cos(\beta-u)=2\left(\frac{I_d X_{c1}}{\sqrt{2}\,E_M}+\cos\beta\right) \tag{20}$$

and substituting equation 20 in 4:

$$E_M=\frac{\pi}{\sqrt{2}}\frac{E_d}{2\left(\frac{I_d X_{c1}}{\sqrt{2}\,E_M}+\cos\beta\right)} \tag{21}$$

from which

$$E_M=\frac{\pi}{2\sqrt{2}\cos\beta}\left(E_d-\frac{2}{\pi}X_{c1}I_d\right) \tag{22}$$

Thus, the voltage drop due to high-frequency overlap can be regarded as an equivalent drop in the direct voltage which is given by:

$$E_{x2}=\frac{2}{\pi}X_{c1}I_d \tag{23}$$

Then, an equivalent direct voltage, including the drop E_{x1}, can be written:

$$E_d'=E_d-\frac{2}{\pi}X_{c1}I_d \tag{24}$$

Substituting for E_d from equation 10:

$$E_d'=E_{d0}-I_d\left(\frac{3}{2\pi}X_{c1}+r+\frac{2}{\pi}X_{c1}\right) \tag{25}$$

The total per cent regulation of the output voltage is therefore:

$$\text{Per cent regulation}=\frac{E_{d0}-E_d'}{E_d'} \tag{26}$$

A convenient expression for calculating the high-frequency voltage under load is obtained by substituting from equations 24 and 25 in 22:

$$E_M=\frac{\pi}{2\sqrt{2}\cos\beta}\left(E_{d0}-I_d\times\left[\frac{3}{2\pi}X_{c1}+r+\frac{2}{\pi}X_{c1}\right]\right) \tag{27}$$

The no-load voltage is obviously:

$$E_{M0}=\frac{\pi}{2\sqrt{2}\cos\beta}E_{d0} \tag{28}$$

The same expression is obtained from equation 4 when $u=0$ and the reactance and resistance drops of the direct voltage are zero so that $E_d=E_{d0}$. In equation 27 E_M is the output high-frequency voltage expressed in terms of the primary voltage of the high-frequency transformer where the primary is considered as being the portion of the winding from the center tap to one terminal.

Grid Control Frequency Response

The inductance of the load coil varies throughout the progress of a heat because of the varying inductance of the charge. The value of this inductance depends upon the size and shape of the metal pieces making up the charge, the magnetic characteristics of the charge material, and its temperature. There are so many variables that it is not practical, at least for melting furnaces, to calculate the resultant inductance except for the empty coil and the coil filled with molten metal. In general, however, in melting nonmagnetic materials the frequency continuously in-

Figure 6. Grid circuit voltage relationships

creases as the pieces successively fuse together until finally a single molten cylinder is formed. In melting magnetic materials, the frequency is lower for a cold-charge of highly magnetic material than for an empty coil and continues so until the charge reaches the Curie-point temperature where the charge becomes nonmagnetic, at which time the frequency rises quite suddenly and then increases gradually until the fully molten condition is reached.

Any phase-shifting circuit consisting of resistance and capacitance or resistance and inductance will give a phase shift which varies with frequency. The grid voltage feedback circuit used for the induction heating converter consists of a resistor, R_g, in series with a capacitor, C_g, as shown in Figure 1. The resistor voltage, E_g, is applied to the grids. In this circuit:

$$\tan\theta = \frac{X_g}{R_g} = \frac{1}{R_g C_g \omega} \tag{29}$$

$$E_g = E\cos\theta = \frac{R_g C_g \omega}{\sqrt{1+(R_g C_g \omega)^2}} \times E \tag{30}$$

It is evident that both the angle, θ, and the magnitude of the grid voltage, E_g, vary with ω. Figure 7 is a circle diagram showing the locus of the grid voltage as the value of the angular frequency, varies. In addition to shifting the phase of the grid voltage, a d-c negative bias is applied to the neutral of the grid transformer so that the voltage from grid to cathode is offset from zero in a negative direction as shown in Figure 6. This negative bias retards the firing angle by an angle:

$$\alpha = \sin^{-1}\frac{E_b}{E_{gm}} \tag{31}$$

Thus, the net angle of advance (or firing angle), β, is:

$$\beta = \theta - \alpha \tag{32}$$

Now, an inspection of the circle diagram shows that as the frequency increases, θ decreases but the magnitude of E_{gm} increases so that E_b/E_{gm} becomes smaller and therefore α decreases. If the bias voltage is small compared to E_{gm}, so that θ is almost equal to β, the latter effect is small, and the net effect is a decrease in β with a resultant decrease in E_M. (See equation 27.) On the other hand, if θ is made nearly 90 degrees (therefore $\alpha \cong 90° - B$), α will change rapidly with ω, and θ, as evident from the circle diagram, will change very little. This means that as ω goes up, β will also increase causing E_M to increase, too. By properly proportioning θ and E_b between these extremes, it is possible to make β approximately independent of ω over the operating range of frequency or, if desired, to produce an "overcompounded" or "undercompounded" effect. This can be seen by a study of the circle diagram.

The small circle with its center at O is made to have a radius equal to E_b when the length of OB represents E_{gm}. OB also represents the phase position of the grid voltage and OA represents the phase position of the anode voltage. The angle which CB makes with OA is:

$$\beta = \theta - \alpha$$

and is therefore equal to the firing angle. It is easily seen that if E_b is proportioned so that CB is tangent to the large circle at B, the angle β will remain approximately constant as the point B moves up or down over a narrow range along the large circle when the frequency varies.

Other methods of compensating for the effect of frequency on the firing angle, β, have been used but have the disadvantage that they rely on a fixed relationship between the load change and frequency change.

Power Relationships in the Load Circuit

The output circuit connected to the high-frequency transformer consists of an inductor coil, L, surrounding the metallic charge and a parallel capacitor band, C, to tune the circuit to the desired frequency. An equivalent circuit for such a load is shown in Figure 8. The resistance R_L represents the power delivered to the charge, the loss in the inductor coil, and the stray losses in the structure surrounding the coil. There is much in the literature[2,7,8] on the theory of current and flux distribution in cylindrical and flat slab loads, and on methods of calculating the equivalent resistance of, and the power absorbed by, such loads and of selecting the best frequency. It will suffice here to say that skin effect causes the current induced in the load to be concentrated near the surface, thereby increasing its equivalent resistance.

This skin effect becomes more pronounced with increasing frequency, causing the power absorbed by the load to increase for a given magnetizing intensity. This is the reason that frequencies higher than 60 cycles are advantageous for most induction heating applications.[9]

The principal applications of mercury-arc frequency-changing equipment at the present time have been for induction melting of alloy steels. In practice, the only conditions for which it is possible to make a reasonably accurate calculation of power input to the furnace are: for an empty furnace; and for a fully molten charge. The case of the fully molten charge then becomes the one of a solid cylindrical charge for which formulae are available for calculating fairly accurately the value of R in Figure 8.[2,7,8,10]

The error will be small if we assume that the circuit will oscillate at the angular frequency $\omega = 1/\sqrt{LC}$ where L is the inductance of the coil with molten charge. Also for typical loads, ωL is of the order of ten times R so that the error is small if I_L is calculated by

$$I_L = \frac{E}{\omega L} = \frac{E\sqrt{LC}}{L} = \frac{E}{\sqrt{\frac{L}{C}}} \tag{33}$$

The power input to the charge is given by

$$P = I_L^2 R = \frac{E^2 C}{L} R \tag{34}$$

As given in the literature[2,7] of induction

Figure 7. Circle diagram of grid voltage

heating

$$R = K_1 N^2 \rho^{1/2} \omega^{3/2} \mu^{1/2} \quad (35)$$

where

ρ = resistivity of the charge

μ = permeability of charge = 1 for molten condition

N = turns in inductor coil. (The term N^2 serves to convert the equivalent resistance of the charge to the reflected value in the coil circuit).

K_1 = a factor involving the dimensions of the charge and coil and the coupling between them.

Therefore

$$R = K\omega^{1/2} N^2 \quad (36)$$

for a given coil and charge.

$$R = \frac{K}{L^{1/4} C^{3/4}} N^2 \quad (37)$$

But

$$L = N^2 L_0$$

where L_0 is the inductance of a single-turn coil of the same dimensions.

Therefore

$$R = \frac{K N^{3/2}}{L_0^{1/4} C^{3/4}} \quad (38)$$

Substituting from equation 38 in equation 34

$$P = \frac{E^2 K C^{3/4}}{L_0^{5/4} N^{3/2}} \quad (39)$$

Therefore

$$P \propto \frac{C^{3/4}}{L_0^{5/4}} \times \frac{1}{N^{3/2}} \quad (40)$$

for constant E.

From equation 40 it is clear that taps in the inductor coil are not a very effective way of adjusting the power absorbed by the coil. The power is seen to vary inversely as the square root of the turns. This is true if the length and diameter of coil and charge are held constant so that L_0 is constant. In the actual case, where turns are tapped back from the ends of the coil a reduction in turns means a decrease in the length of the coil with a corresponding increase in L_0 and the power, P, will change even less than indicated by equation 40.

This is not the case for motor-generator set where the frequency is fixed. In that case, making the same simplifying assumptions as before,

$$I_L = \frac{E}{\omega L} = \frac{E}{L_0 N^2} \quad (41)$$

where

$$\omega = 2\pi f$$

$$R = K' N^2 \quad (42)$$

since ω in equation 36 is now constant.

$$P = I_L^2 R = \frac{K' E^2}{\omega^2 L_0^2 N^2} \quad (43)$$

Therefore,

$$P \propto \frac{1}{L_0^2 N^2} \quad (44)$$

for constant E and ω.

For equation 44, it is clear that in this case taps will be an effective means of adjusting power, although frequent switching of capacitors carrying heavy currents is required to keep the circuit tuned to the generator frequency.

It is of interest to make a similar comparison for operation of two furnaces in parallel from one high-frequency power supply.

Equations 39 and 43 can be rewritten substituting $L = L_0 N^2$ for the inductance of the load coil. Then for the self-excited converter

$$P = K E^2 N^2 \frac{C^{3/4}}{L^{5/4}} \quad (45)$$

and

$$f_1 = \frac{1}{2\pi C^{1/2} L^{1/2}} \quad (46)$$

For the motor-generator set

$$P = K' E^2 N^2 \frac{1}{\omega^2 L^2} \quad (47)$$

and in order to maintain unity power factor of the motor-generator circuit, it is essential that

$$C = \frac{1}{\omega^2 L} \quad (48)$$

Suppose that an installation consists of one high-frequency power source and two or more identical induction furnaces and that it is desirable to operate any one furnace alone or two furnaces in parallel. If the inductance of each furnace is L, then by equation 45 the power drawn by a furnace operating alone will be (for a self-excited converter):

$$P_1 = K E^2 N^2 \frac{C^{3/4}}{L^{5/4}} \quad (48a)$$

Figure 8. Equivalent high-frequency load circuit

Assume that P_1 is the allowable input to the charge. With two identical furnaces in parallel, each furnace can be considered as oscillating with one-half the total capacitor bank, C, so that the power, P_2, drawn by one furnace with two operating simultaneously is

$$P_2 = K E^2 N^2 \frac{\left(\frac{C}{2}\right)^{3/4}}{L^{5/4}} = 0.595\, K E^2 N^2 \frac{C^{3/4}}{L^{5/4}} \quad (49)$$

$$P_2 = 0.595 P_1 \quad (50)$$

The total power drawn by both furnaces will be

$$2P_2 = 1.19 P_1 \quad (51)$$

The total power has increased about 19 per cent. It will be necessary to reduce the voltage (by one of the methods described before) only about 10 per cent in order to bring the total power down to the rating of the converter.

The frequency will increase about 40 per cent as shown by equation 46.

$$f_2 = \frac{1}{2\pi \left(\frac{C}{2}\right)^{1/2} L^{1/2}} = \frac{\sqrt{2}}{2\pi C^{1/2} L^{1/2}} = \sqrt{2} f_1 \quad (52)$$

Looking at equation 47, for a motor-generator set, the power for one furnace alone is

$$P_1 = K' E^2 N^2 \frac{1}{\omega^2 L^2} \quad (53)$$

and for two furnaces in parallel the total inductance will be $L/2$ and it will be necessary as shown by equation 48 to double C in order to bring the circuit back to unity power factor at the generator frequency. Then the power drawn by each furnace alone will be the same as before, and, in order to bring the total power down to the rating of the machine, the voltage, E, must be reduced to approximately 70 per cent of the original value or the power to each furnace must be cut in half by inserting extra turns in the inductor coils.

Efficiency

The conversion efficiency is usually specified as that from the three-phase, a-c input line terminals to the single-phase a-c output transformer terminals. The principal losses in this circuit are the copper and core losses in the transformer elements, the arc drop loss in the mercury-arc converter, and the auxiliary power requirements for the converter unit. The copper and core losses at full load average from five per cent to seven per cent, dependent upon design considerations. The arc drop loss is of the

Figure 9 (left). Typical arrangement of induction melting equipment

Figure 10 (above). Typical chart of power input to melting furnace

order of 1.5 per cent, and the auxiliary power needed is about 1.5 per cent. Thus, the conversion efficiency at full load is better than 90 per cent. The efficiency curve at lighter loads has the same type of characteristic as that for mercury-arc rectifier equipment, remaining relatively flat at better than 90 per cent from full load to about one-quarter load.

The over-all efficiency obtained in converting alternating electric power into heat induced into the charge is dependent upon additional losses in the capacitor and heating-coil circuit. The loss in the capacitors is generally of the order of three per cent and is dissipated by water cooling. The loss in the heating coil is dependent upon design and operating conditions, and varies considerably with different types of applications and in heating different types of metals. Under the best conditions, the heating-coil efficiency may be as high as 85 per cent and in general it is better than 75 per cent for steel melting. The over-all efficiency therefore will be in the range of 65 to 80 per cent.

Description of Equipment

Installations of 300-kw and 600-kw mercury-arc frequency-changing equipment have been made in several foundries in the United States for induction melting of approximately 1,000 to 2,000 pounds of alloy steels and high-grade nonferrous alloys per hour. Furnaces range in capacity from 200 pounds to one ton.

A typical installation of 300-kw equipment, as shown in Figure 9, consists of a circuit breaker for connection to the incoming three-phase power line, a transformer consisting of three separate transformer elements assembled within a single oil-filled case, the mercury-arc converter unit, a control cubicle, a capacitor bank, and usually two or three furnaces with inclosed disconnecting switches. The circuit breaker and transformer are installed outdoors adjacent to the building or indoors within the substation containing the other electrical equipment. The furnaces are located in the melting department in the main foundry building.

The transformer is equipped with radiators and is self-cooled. The mercury-arc converter is water-cooled, and is provided with automatic temperature regulation and protection equipment. The capacitors and furnace coils are also water-cooled.

Operation of the equipment is under control of the melter at the control cubicle panel behind the furnaces. To place the equipment in service, the electrically operated circuit breaker is closed to energize the 60-cycle transformer, and then a starting relay is operated to release the negatively biased grids of the mercury-arc converter unit so that it will start oscillating.

In melting service, voltage control is of importance during the melt-down period in order to maintain automatically as close to maximum rated power as possible. The type of metal (magnetic or nonmagnetic), the size of pieces, compactness of charging, the thickness of the lining, and other factors all have a bearing on the amount of power induced into the charge in the furnace. A small automatic regulator functioning in the high-frequency grid phase-shifting circuit has been used to maintain constant voltage on the furnace coil. More recently a static-type grid-control circuit has been devised for several installations so as to make them inherently self-regulating with respect to the high-frequency output voltage.

At the conclusion of a heat, when the furnace charge is completely molten and raised to the desired temperature, power is removed by interrupting the alternating high-frequency voltage fed back to the grids of the mercury-arc converter. After deoxidation of the molten metal, power can be reapplied at one-half voltage by means of a tap changer on the high-frequency transformer or by 60-cycle phase control of the converter grids. This provides about one-quarter power which is sufficient to offset conduction and radiation heat losses and thus maintain the molten metal at a relatively constant temperature until the complete charge has been poured. A typical graphic chart of the kilowatt input to the furnace during melting of a charge and the batch pouring of molten metal is shown in Figure 10.

Installations of mercury-arc frequency-changing equipment can be designed for connection to any available power-line voltage. The inherent self-tuning characteristic results in simple operation with relatively little attention required from the furnace operator.

Appendix

C = capacitance of tuned load circuit
C_g = capacitance of grid phase-shifting circuit
E = effective value of high-frequency load-circuit voltage
E_b = direct bias voltage applied to grids
E_d = direct voltage under load
E_{d0} = direct voltage at no-load
E_d' = equivalent direct voltage including drop due to high-frequency overlap
E_g = effective value of alternating component of high-frequency grid voltage
E_{gm} = peak value of E_g
E_M = effective value of high-frequency transformer-primary voltage from center tap to one terminal
E_{M0} = E_M at no-load
E_m = peak value of E_M
E_r = drop in direct voltage due to transformer and reactor copper losses
E_s = effective value of no-load phase-to-neutral voltage of 60-cycle transformer secondary
E_{s1} = drop in direct voltage due to 60-cycle overlap
E_{s2} = drop in direct voltage due to high-frequency overlap
e_{a0} = instantaneous voltage from center tap of high-frequency transformer to anode 1
e_{a2} = instantaneous voltage from center tap of high-frequency transformer to anode 2
e_{k1} = instantaneous voltage from anode 1 to cathode
e_{k2} = instantaneous voltage from anode 2 to cathode
f = frequency of output voltage
f_1 = output frequency—one furnace operating alone
f_2 = output frequency—two furnaces in parallel
I_c = effective value of extrapolated commutating current = E_M/X_{cl}
I_{cm} = peak value of I_c
I_d = cathode current
I_L = effective value of heating-coil current
L = inductance of tuned load circuit
L_{cl} = high-frequency transformer commutating inductance in primary terms
L_e = equivalent inductance of single-turn coil having same dimensions as heating coil
N = heating coil turns
P = power input to charge to be heated
P_1 = power to charge—one furnace operating alone
P_2 = power input to one charge when two furnaces are operating in parallel
P_r = total copper losses of 60-cycle transformer, high-frequency transformer, and cathode reactor
$Q = L/R$ of heating coil
R = equivalent resistance of charge as seen from coil terminals
R_g = resistance in grid phase-shifting circuit
r = equivalent of direct voltage drop due to copper losses
u = angle of high-frequency overlap
X_{cl} = 60-cycle transformer commutating reactance in secondary terms
X_{cl} = high-frequency commutating reactance in primary terms
X_g = capacitive reactance in grid phase-shifting circuit
α = displacement of firing angle due to bias voltage
β = angle of advance, or firing angle
ϵ = base of Naperian logarithms
θ = phase displacement in grid phase-shifting circuit between E_g and E
μ = magnetic permeability of charge
ρ = electrical resistivity of charge
τ = time constant of damped sine wave of output voltage
ϕ = margin angle = $(\beta - u)$
ω = natural angular frequency of tuned load circuit angular operating frequency
ω_o = angular frequency of commutating voltage and current

Aging Characteristics of Dry-Type Transformer Insulation at High Temperature

H. C. STEWART
MEMBER AIEE

L. C. WHITMAN
MEMBER AIEE

INSULATIONS used in class B insulated dry-type transformers consist of such materials as glass yarn and sheet asbestos and even cellulose in combination with a heat-resistant varnish. The life characteristics of such insulation with particular reference to the gas medium in which the material is required to function is discussed in this paper. Further data on the aging of this insulation will be available when the co-operative aging tests that are being conducted under the supervision of the working group of the AIEE transformer committee are completed.

The life of any material is dependent not only upon its temperature but also upon the medium in which that temperature is attained. There is a fundamental difference in the life of insulation containing organic materials operating in an insulating liquid or in a gas medium. In the former instance, the material ages mechanically, but by virtue of liquid absorption, it maintains its electrical strength to a remarkable degree if undisturbed by vibration. In the latter case where the material operates in a gas medium, there is not only a reduction in the mechanical strength but in the electrical strength as well. This latter situation results from the aging of the varnish impregnant used to impart high dielectric and mechanical qualities to the base material. In the process of deterioration, the varnish is replaced by air which has a much lower dielectric strength.

Engineers are conscious of the fact that the reduction in dielectric strength of electric apparatus can be serious since it encroaches upon the factors of safety originally designed into such equipment. Such loss renders the apparatus less likely to withstand the more severe operating conditions, such as lightning, switching surges, and short circuits.

Recognition of these conditions leads to the conclusion that dielectric strength is a dominant factor in evaluating the life of insulations aged in a gas medium. On this premise, a percentage of the initial dielectric strength, at operating temperature, has been chosen as the criterion. The value of this percentage selected as indicative of insulation life is arbitrary. An approach to 50 per cent reduction is increasingly dangerous and may well represent the end of life. The major part of these data, therefore, is predicated on the end of life occurring at a point where the dielectric strength has diminished to one-half of its initial value at operating temperature.

Data are presented on both class A and class B insulations subjected to temperatures in excess of presently-established operating levels. From these data, extrapolation can be made to indicate anticipated life at normal operating temperature. The results shown here indicate the maximum life which can be expected from insulations when maintained continuously at a given operating temperature. Intermittent operation may introduce other conditions, such as moisture absorption, contamination of the operating medium, and so forth, which will be a factor in further reducing the life beyond that indicated by these data.

Finally, these data and arbitrarily assumed load cycles are used to estimate the life of a dry-type transformer.

Paper 48-289, recommended by the AIEE transformer committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted July 29, 1948; made available for printing September 10, 1948.

H. C. STEWART and L. C. WHITMAN are both with the General Electric Company, Pittsfield, Mass.

Material Investigated

The varnish impregnant used is a heat-resisting type and is specifically referred to hereafter as a high-temperature phenolic varnish.

The following list is a specification of the materials tested.

1. Commercial grade of sheet asbestos.
   Thickness—15 mils.
   Impregnant—high-temperature phenolic varnish.
   Cooling medium—air at atmospheric pressure.
2. Commercial grade of sheet asbestos.
   Thickness—15 mils.
   Impregnant—high-temperature phenolic varnish.
   Cooling medium—nitrogen at 5 pounds gauge pressure.
3. Fiber glass yarn.
   Thickness—20 mils.
   Impregnant—high-temperature phenolic varnish.
   Cooling medium—air at atmospheric pressure.
4. Electrical grade of black-varnished cambric.
   Thickness—7 mils.
   Impregnant—no additional.
   Cooling medium—air at atmospheric pressure.
5. Electrical grade of kraft paper.
   (Grade used in insulating cylinder)
   Thickness—4 mils.
   Impregnant—high-temperature phenolic varnish.
   Cooling medium—air at atmospheric pressure.

The curing time and temperature for the sheet-asbestos and glass-yarn test pieces are those recommended by the manufacturer for curing the high-temperature phenolic varnish used. In the case of the kraft-paper test pieces, the curing was accomplished by a reduction of temperature with an increase in duration of cure to prevent deterioration of this class A material.

Figure 1. Component parts of insulation life test piece

Figure 4. Initial dielectric strength asbestos sheets

These are representative of some of the class A and class B transformer insulations used as winding layer material, wire covering, and insulating cylinders. While only a few of the possible combinations were tested, they are believed to be a fair representation of the insulations used in dry-type transformers and other air-insulated apparatus.

Choice of Test Pieces

The physical arrangement of the test material was selected to satisfy the following conditions:

1. Use of material in customary form.
2. Convenient and accurate measurement and control of the temperature of the test piece.
3. Provision for applying the dielectric test to the entire test piece.
4. Temperature gradients in test piece comparable to those encountered in practice.
5. Inclusion of oxidation effects on the test piece by exposure to normal ambient conditions.
6. Visual inspection of test piece for check on mechanical effects, such as crazing or cracking.
7. A structure that could be treated and handled as a unit without danger of damage to the insulation.

These requirements are realized in a practical sense in the test piece used and described in the following.

Details of Test Piece and Testing Technique

The heat source consisted of a 2-inch diameter metal tube housing a calrod-type of heating unit, Figure 1. Uniform heat conduction from the heating unit to the tube was facilitated by a magnesium oxide filling.

Temperatures of the inner surface of the insulation were obtained from thermocouples brazed at intervals along the tube.

Temperatures of the outer surface of the insulation were measured with thermocouples brazed to the narrow external electrodes which cover the insulation areas under test, Figure 2. Outer thermocouples, usually greater in number, were located directly over the tube thermocouples, so that it was possible to plot temperature gradients parallel with the inner and the outer surfaces. Precautions were taken in every instance to see that thermocouple leads did not conduct heat from the thermocouple junction, thereby affecting the temperature accuracy. This was accomplished by associating at least six inches of the thermocouple leads with the junction temperature. The complete assemblies were supported horizontally with thermocouples along the upper, or "12 o'clock," surface. Figures 1 and 2 show partial and complete assemblies of the test piece.

The number of turns of insulation wound on the tube was determined by the dielectric strength of the material. Insulation thickness was selected so that the voltage was sufficient to minimize the erratic breakdown behavior of small spacings. Usually this resulted in a minimum of 2,000 volts and a maximum of 4,000

Figure 2. Partial and complete assembly of insulation life test piece

Figure 3 (below). Insulation life test piece using glass-covered wire

Figure 5. Summary of initial dielectric strength in air at atmospheric pressure

volts where the 50 per cent criterion is used.

Dielectric tests were applied at periodic intervals between the tube and each outer electrode with temperature maintained continuously.

In addition to sheet material representative of layer insulation, glass-fiber yarn was used as turn insulation on copper wire. The insulated wire was wound on a tube prepared in a manner similar to that used in the assembly of test pieces with sheet insulation. Outer electrodes were fastened over the insulated wire. The

Figure 7. Thermal drops through fiber glass yarn on copper wire

copper conductor was grounded to the tube so that dielectric tests could be made between the outer electrodes and the copper conductor. Figure 3 shows a complete test piece.

The sheet asbestos and kraft papers were preimpregnated but cured only to a tacky state before being wound on the tube. After the outer electrodes and thermocouples were added, the assemblies were vacuum treated with a high-temperature phenolic varnish and fully cured.

Sheet black-varnished cambric was placed on the tube in its original form and received no subsequent impregnation.

The fiber glass-yarn turn insulation had included varnish which acts as a lubricant to prevent abrasion during the winding operation. The complete assembly received the varnish impregnation under vacuum.

Criterion of Life of Insulation Operated in a Gas

This paper proposes that the end of expected life of insulation when operated in a gas medium be considered as reached when the dielectric strength (referred to on figures as initial hot dielectric strength) has decreased to 50 per cent of the initial value with a given temperature maintained. This is an entirely arbitrary selection based on such general considerations as initial insulation level of air-insulated apparatus; exposure of this apparatus to transient voltages as affected by usual location and application; and of allowance of the decrease of factor of safety to a dangerously low value. As a matter of general interest, some data are also given for decrease of dielectric strength to 75 per cent of initial strength.

Determination of Initial Dielectric Strength at Test Temperature

With the insulations tested it was first necessary to determine the initial dielectric strength as a function of temperature, that is, the dielectric breakdown of the insulation the first time it was brought up to the testing temperature. Most of these data are based on 60-cycle 1-minute holding tests. However, there might be some controversy as to whether the determination of the initial dielectric strength should be made using a 1-minute holding test or a momentary test. Therefore, data were taken on both bases. The 1-minute tests were made starting at approximately 60 per cent of the anticipated strength and holding voltage for one minute. This voltage was increased in approximately 10 per cent increments, holding each step one minute until failure occurred. This maximum voltage at failure is considered to be the initial dielectric strength at operating temperature. Momentary tests were made using a rate rise of 1/2 kv per second as recommended by American Society for Testing Materials Standards.[1] All initial breakdown tests were reduced to a volts-per-mil basis, using the average of ten measured thicknesses for each test piece.

Method of measuring thickness of insulation is described in American Society for Testing Materials Standards[2] except that in case of turn insulation, standard machinist's micrometers with 1/4-inch diameter anvils were used.

Typical data for asbestos are shown on Figure 4. Composite curve, Figure 5, covers all material tested.

The possible advantage of the momentary test is that corona is minimized. The disadvantage is that it is not as searching a test as the 1-minute test and does not give opportunity for thermal failure which may be encountered in practice. For many years, the 1-minute holding test has been the standard for factory acceptance tests. This factors the thermal effect particularly important in class B asbestos insulations operated in air.

Table I

Watts Per Sq.in. Determination of the Criterion Voltage for Breakdown of Insulation Life Pieces

Knowing the average insulation thickness, the initial breakdown voltage was calculated from Figure 5. Then the breakdown test voltage was taken as 25, 50, or 75 per cent of the initial breakdown voltage, depending upon which figure was chosen as the criterion of life. Both the 1-minute and momentary tests were made at time intervals of approximately two per cent of the anticipated life of the insulation. For the momentary tests, the voltage was increased at the rate of rise of 1/2 kv per second and, on arrival at desired level, was reduced at the same rate.

Temperature Determination

A complete measurement of all thermocouples was made as soon as temperature

Figure 8 (left). Chamber for testing insulation pieces in inert atmosphere

equilibrium had been attained on each test piece. These were plotted then as shown on typical curves in Figure 6. The average insulation temperatures, existing for each test point, were calculated by averaging the corresponding reading from the maximum to minimum temperature curves.

It will be noted that considerable radial gradients are indicated from the thermocouple in the tube wall to the thermocouple on the outer electrode. The point might be raised whether these gradients are actually in the insulation itself or whether they might be largely in a theoretical air film each side of the insulation. To investigate this, several test pieces were made up with different numbers of layers of insulation. The watts input to the heating unit was measured and the temperature determined.

From these data, the degree temperature drop-per-mil insulation thickness was calculated, Table I. It is seen that these values are approximately the same without regard to number of layers, showing that gradients are in the insulation itself and only small surface film drops exist. Also, temperature resistivities of approximately 250 degrees centigrade per watt per square inch per inch, for impregnated asbestos were determined which approximately check the values of similar insulation.[3]

There remains the circumferential temperature gradients on these test pieces. Table II shows result of tests with thermocouples placed around tube and outer electrodes. It is seen that these differences are small; the maximum temperature on the bottom being only about 2.5 per cent more than that on the top. In examining pieces that failed, records were kept as to the position of failure. No particular pattern or trend was noted in these records.

In the case of the fiber glass wire pieces, the average insulation temperature was determined by taking 25 per cent of the difference between the tube temperature and the outer electrode temperature and adding this 25 per cent to the outer electrode temperature. That this is a proper procedure will be clear from Figure 7 and the following considerations.

The temperature gradients here can be considered in three parts:

1. Gradient from the metal tube to the copper through the insulation between the tube and the copper.
2. Gradient through the copper wire itself.
3. Gradient from the copper wire to the outer electrode through the insulation between the copper and the outer electrode.

It is at once evident that items 1 and 3 are equal in magnitude from symmetry, neglecting small differences due to curvature. Let us compare the thermal drop through item 2 compared with the sum of those through items 1 and 3.

The thermal resistivity of copper is 0.1125 degree centigrade per watt per cubic inch, while that of fiber glass is approximately 250 degrees centigrade per watt per square inch per inch.

The thermal drop through the copper can be neglected since its thermal resistance is roughly 1/1,000 of that through the fiber glass for the thicknesses involved. Since we are applying the dielectric test between the outer electrode and the wire, we are interested in the average temperature of the outer portion only; that is, that of item 3. Again from symmetry, the average temperature of this region is the temperature of a point halfway from

the copper wire to the outer electrode, which is 25 per cent of the effective thermal distance and hence 25 per cent of the temperature drop from outer electrode to tube surface. Again, we are neglecting the correction for curvature, which would be negligible.

The voltage supply to the heating unit in all cases was maintained at a uniform value by means of voltage stabilizer units so that heating was essentially constant. The ambient temperature was closely maintained by auxiliary heat and exhaust fans, both thermostatically controlled. The variation of the temperature of the insulation under test was not more than five degrees from the average value over any 24-hour period, and for practically all the time the variation was less than two degrees.

Tests Made in Inert Gas

Most of the data in this paper were obtained with the samples exposed to free air at atmospheric pressure.

In order to see the effect of oxygen on the rate of deterioration, some units were sealed in a chamber in pure nitrogen. The units were constructed in the same manner as all others and electrodes brought out of the sealed chamber for dielectric tests and for supplying heating current.

Temperatures of all parts of the unit were determined by thermocouples as in previous tests. The gas pressure was set at five pounds gauge to insure the purity of the nitrogen gas. Also, this would be a possible operating condition for a sealed dry-type transformer. Construction of this chamber is shown in Figure 8.

Results to date indicate that the life of impregnated asbestos operated in this manner is considerably lengthened, at least for temperatures above 200 degrees centigrade. No failures in the insulation

Figure 13. Life characteristics—asbestos sheets

have yet occurred in the elapsed testing time which is roughly three times as long as that for similar insulation operating in free air at the same temperature. This would seem to allow an increase of at least 25 degrees centigrade in hot-spot temperature for class B insulation, operated in an inert atmosphere, with normal life. Whether the relation holds for lower temperatures is not yet known as not enough data are available to determine the "degree rule." This relation may or may not hold for other insulations, although some improvement is probable.

Results

1. Figures 9 to 19 inclusive, give the life characteristics of the various insulations investigated in this research. It is to be noted that in all cases these are plotted with the hours to breakdown on the logarithmic y axis, but that the average insulation temperature is plotted on the uniform x axis with an evenly divided degree-centigrade scale, Figures 9 and 10; and also with a reciprocal absolute temperature scale,[4] Figures 11 to 19 inclusive. The latter gave straight-line characteristics, allowing greater ease in extrapolation.

2. Summary of all life characteristics is given in Figure 9 and Figure 11 plotted as a function of temperature in degrees centigrade, and reciprocal absolute temperature degrees centigrade, respectively.

3. Extrapolation of these data on class B material to 130 degrees centigrade continuous operation shows that dielectric strength is reduced to one-half of its initial value in 3 to $4^1/_2$ years, where insulations operate in a gas medium, see Table III.

4. Extrapolation of these data on class A material to 105 degrees centigrade continuous operation shows that dielectric strength is reduced to one-half of its initial value in approximately two years, where insulations operate in a gas medium, see Table III.

5. The so-called degree rule (degrees increase in temperature to reduce life 50 per cent) of insulations operated in a gas medium changes markedly depending upon the class of insulation and its operating temperature.

6. Degree rule for class A insulations[5] in a gas medium is indicated as halving the insulation life for each approximately 10 degrees centigrade increase in the range of 105 to 150 degrees centigrade, Figure 20.

7. Degree rule for class B insulations in a gas medium is indicated as halving the life for each approximately 13 degree centigrade increase in the range of 130 to 200 degrees centigrade, Figure 20.

8. It is interesting to note that in general, the life of class B materials is ten times that of class A materials operated in a gas medium at the same temperature, see Figures 9 and 11.

9. If a life criterion at 75 per cent of initial strength is used instead of 50 per cent, a further shortening of life of about 10 per cent will result, see Table III.

Evaluation of Data in Terms of Dry-Type Transformer Life

Extrapolation to 130 degrees centigrade as shown in Table III indicates that the initial dielectric strength is decreased to half value for class B insulations in 3 to $4^1/_2$ years of continuous operation. The variation in years is due to the individual material and the method of extrapolation employed. A value of 30,000 hours (3.4 years) is obtained considering asbestos and the inverse absolute temperature[6] extrapolation, which appears to be the more accurate method.

Dry-type transformers are seldom loaded to capacity for more than 8 out of 24 hours and so do not operate at ultimate temperature for more than about 5 out of 24 hours, due to inherent thermal capacity. Since these data are obtained on the basis of continuous operation, it is, therefore, necessary to introduce a factor which evaluates these data in terms of life where a transformer does not operate at maximum temperature continuously. Based on the foregoing assumption, dry-type transformer life in terms of these data can be assumed to be increased 24/5 or 4.8 times. This is equivalent to saying that a dry-type transformer operating on this load cycle and attaining a hot-spot temperature of 130 degrees centigrade will

Figure 20. Variance of degree rule with temperature

Insulation in air at atmospheric pressure (Derived from Figures 12 to 19 inclusive)

Asbestos and kraft paper sheets, and fiber glass yarns are impregnated with high temperature phenolic varnish

have expected life of $(4.8 \times 3.4) = 16.3$ years. Moreover, maximum ambient conditions would seldom exist for more than 50 per cent of the time. This would also tend to increase the life expectancy since insulation deteriorates at a lesser rate at lower temperatures. A 10 degree reduction in ambient would result in a hot-spot temperature of 120 degrees centigrade. From Figure 13, life at 120 degree centigrade is 57,000 hours (6.5 years) for continuous operation. For the load cycle of 8 hours (5 hours effective) operation out of 24 hours, the expected life at 120 degrees centigrade becomes $24/5 \times 6.5$ years $=$ 31.2 years. Then, assuming that the transformer operates one-half the time at the lower ambient, which results in 120 degrees centigrade temperature, and the remainder of the time at 10 degree higher ambient, resulting in 130 degrees centigrade temperature, the expected life becomes

$$\frac{1}{1/2(1/16.3)+1/2(1/31.2)} = 21.4 \text{ years}$$

This is a reasonable situation and parallels experience in the field with liquid-filled transformers. It is interesting to note that if this same class B dry-type transformer is designed for a 160 degrees centigrade hot-spot temperature with the same 10 degrees centigrade ambient fluctuation, its life for continuous operation from Figure 13 is as follows:

150 degrees centigrade—9,200 hours—1.05 years.

160 degrees centigrade—5,200 hours—0.59 years.

For the condition where the transformer operates one-half at each temperature and for the previously assumed loading cycle, the expected life is

$$\frac{24}{5}\left[\frac{1}{1/2\left(\frac{1}{1.05}\right)+1/2\left(\frac{1}{0.59}\right)}\right] = 3.63 \text{ years}$$

This is one-sixth of the estimated life at 130 degrees centigrade.

The deterioration of class B insulation for overload conditions for various periods has been calculated on the basis of the following criteria and is shown in Figure 21.

1. End of life as 3.4 years when operated continuously at 130 degrees centigrade.

2. Deterioration rate, incremental degrees to halve life, at temperatures in excess of 130 degrees centigrade as on Figure 20.

This is a useful guide to assess the injury to insulation operated at a temperature in excess of 130 degrees centigrade.

Data from Table III and Figure 11 indicate a 30 per cent or 5-degree advantage for glass yarn over commercial grades of asbestos. This is undoubtedly due to contaminants in the asbestos and can be circumvented by the use of refined grades of asbestos or Terratex.[6]

Conclusions

1. A new method of determining the life characteristic of insulations operated in gaseous mediums has been developed. In this method, failure voltage at operating temperature expressed as a percentage of the initial breakdown voltage has been used as a criterion of the length of life. The results are self-consistent and constitute a valuable and accurate tool, yielding results in terms of voltage strength which is of major importance in electric apparatus.

2. In voltage testing to breakdown, the question of effect of corona on life has been raised where tests are of 1-minute duration. In this investigation, the results in terms of hours of operation are substantially the same for either momentary or 1-minute applications of voltage.

3. These data support the chemical deterioration theory[4] that the logarithm of time to reach a particular percentage of the dielectric strength of insulation is

Figure 21. Loss of life in air—asbestos sheets impregnated with high-temperature phenolic varnish

proportional to the reciprocal of the absolute temperature.

4. Based on our data, it appears unwise to consider continuous operating hot-spot temperatures in excess of 130 degrees centigrade for class B insulations in use at the present time.

5. Considering the normal operating temperatures encountered by dry-type transformers due to normal load cycles and ambient fluctuations, it has been shown that such a transformer operated at not over 130 degrees centigrade hot-spot temperature will have a life comparable with the normal liquid-filled transformer.

Discussion

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): When a new insulating material is introduced on large-scale production there are two general methods open for the selection of the maximum or limiting hottest spot temperature of the insulation. One method is to select a temperature limit based on available laboratory data, which may be exceedingly limited, and use this limit in designing transformers, hoping that several years experience will show that the temperature limit is safe. The second method is to base the temperature limit on the result of extensive laboratory aging tests on the insulating material.

The experience method of determining the limiting insulation temperature for a reasonable length of time is exceedingly difficult of application, and requires a long time—20 years or more. Carefully kept records of loading and ambient temperatures covering many installations are needed as well as an exceedingly high degree of skill and ability in the analysis of the records.

The laboratory test method is also difficult of application. It requires that some characteristic of the insulation, mechanical or electrical, be selected as the basis of comparison of the effects of various temperatures and time. It also requires that some arbitrary value of the selected characteristic, in relation to its initial value, be chosen as the end point of the useful life of the insulation. It needs, too, the exercise of sound engineering judgment tempered by experience to translate the test results into design limits for the industry.

The use of class B insulation is, of course, not new. AIEE Standards have defined class B insulation and for many years the maximum temperature has been set at 130 degrees centigrade. Class B insulation has been used in rotating machinery for many years, but its use in moderate sized dry-type power transformers started at a fairly recent date, some eight or ten years ago.

The question of whether 130 degrees centigrade hot-spot temperature was the correct value for dry-type transformers was debated for several years in the AIEE transformer subcommittee (now the transformer committee) without getting anywhere. To settle this question it was decided by the transformer committee to start some co-operative aging tests in various laboratories. A working group, who had carried out co-operative aging of class A insulation, was requested to undertake this job of making laboratory tests on classes B and H insulation. Today four laboratories, General Electric, Westinghouse, Allis-Chalmers, and Dow-Corning, are co-operating in the making of these tests.

As previously stated, the two available methods for determining the maximum temperature limit for a new insulation are laboratory tests and experience in the operation of transformers. To obtain the final answer for classes B and H insulations will probably require results obtained by both methods.

The very complete data presented in the paper by Stewart and Whitman are, of course, in the laboratory class. These tests were started approximately $1^1/_2$ years before the AIEE working group was requested to start its co-operative aging tests on classes B and H insulations.

I feel that exhaustive laboratory tests, similar to these tests or to the test that will be finally agreed upon by the working group, are absolutely necessary. The authors are to be highly commended for presenting the very complete data in their paper. The results should serve as a "bench mark" for many years to come.

As a final check on their work, and on the work that has been carried on in the Westinghouse Laboratory at East Pittsburgh, the working group is planning on making further pilot tests to decide on a final method for evaluating the effect of temperature on these insulations. When this point is settled the main program of tests will be carried out.

T. R. Walters (General Electric Company, Pittsfield, Mass.): The authors have presented an interesting addition to the relatively meager literature on aging characteristics of class B insulations.

For the past several years we have been carrying out, in the laboratory at Pittsfield, aging tests on various class B insulations independently of the tests carried out by Stewart and Whitman. Our tests were carried out in circulating air ovens at temperatures of 150, 175, and 200 degrees centigrade. Reference to some of the earlier data at 175 degrees centigrade was given in a paper by T. R. Walters.[1]

Although various criteria have been used for determining the end of the useful life of insulation, we believe that one important factor in the life of dry-type apparatus is humidity. As long as the apparatus is in service, it will remain fairly dry. However, if it is shut down for weekends or other extended periods, the insulation depends on its varnish treatment for moisture protection. Accordingly, our laboratory tests were set up so as to periodically measure power factor of the samples after 24-hours exposure to 90 per cent relative humidity at 90 degrees Fahrenheit, as a check on the effect of high temperature aging. A "runaway" power factor condition at high humidity was taken as the end-point of insulation life.

The advantages of this method of judging end-point are that the break in the power factor versus time curve is relatively sharp; power factor values are not affected to any great extent by differences in the size of samples; and small imperfections in the samples are averaged out.

Comparing our data with that shown by Stewart and Whitman, we find that we are in general agreement, even though our tests were carried out quite independently, using a different test procedure and a different criteria for the end of useful life. The same insulations and high temperature varnish were used. The authors data indicate a "degree rule" of 13 degrees centigrade for this class of insulation. Our results showed a slightly higher "degree rule," 14 degrees centigrade or higher, with a somewhat shorter life at any given test temperature. The shorter life may be partly explained by the fact that our tests were run in an oven, where the samples were at a uniform temperature throughout, while the authors simulated service conditions where there was a temperature drop through the insulation.

In any event, our data tends to corroborate Stewart and Whitman's conclusion that 130 degrees centigrade is about the maximum hot spot temperature that can be permitted in dry-type class B insulated apparatus operated in free air, if the usual useful life is to be expected in service.

REFERENCE

1. See reference 6 of the paper.

H. C. Stewart and L. C. Whitman: T. R. Walters has indicated that humidity may have a bearing on the life of insulations operating in free air. We purposely omitted the humidity angle since we were interested in the maximum life of insulating materials. It is possible that apparatus may be operated continuously, either with or without load, in which case there will be sufficient heat to prevent condensation and water absorption. Under such conditions, humidity will have little effect on insulation life. Should there be heating and cooling periods due to shutdown, then humidity can be an unfavorable factor. Both conditions should be considered eventually, but it is more important to consider the most favorable condition when consideration is directed to the increase of the temperature limit for class B insulation. It is gratifying to find that the two methods result in general agreement as to life of this type of material. It would appear that dielectric tests are sufficiently searching and that the complication of humidity may not be justified. The particular advantage of the method we proposed lies in the fact that life is evaluated in terms of the original dielectric strength and so is easier to interpret than resistance and power-factor tests.

V. M. Montsinger has commented on the difficulties encountered in setting up temperature limits for insulation. We have attempted to show that the established 130 degrees centigrade hot-spot temperature should not be exceeded in dry-type transformers.

Further information may substantiate the use of higher temperatures for class B insulations in inert atmosphere than is permissible when they are exposed to the oxygen of air.

We hope that the data presented here will be of assistance to the AIEE working groups in their evaluation of the effect of temperature on class B insulation.

Measuring Transformer Winding Temperatures Continuously with the Transformer Carrying Load

A. M. LOCKIE
MEMBER AIEE

G. M. STEIN
MEMBER AIEE

Synopsis: Conventional test methods are not sufficiently accurate for the measurement of heating transients in transformer windings when high or rapidly changing temperatures are involved. For resistance measurements made after shutdown, the accuracy is increased by improved methods of evaluation which may be based on a cooling curve or on a single test point. These calculations are somewhat laborious, and are limited in accuracy and usage. For this reason, suitable connections are described for testing winding temperatures with d-c bridges throughout any load cycle, with or without the application of a-c line voltage. This technique applies to the factory test of single or polyphase transformers and will measure the temperatures in two or more windings simultaneously. Test results of temperature transients obtained by this new method are included in curve form.

PRESENT standards impose only one restriction on the temperatures in transformer windings, namely, that the average rise above ambient temperature shall not exceed a specified amount, usually 55 degrees centigrade, under continuous operation at rated load.[1] Consequently, the only temperature test, commonly made, demonstrates whether this requirement has been met. Under these conditions, the winding temperatures are low, and thermal equilibrium is reached before readings are taken, so that a resistance test, obtained within a reasonably short time after shutdown, usually gives sufficiently accurate results for commercial purposes.

Since the permissible winding rise has a fundamental effect on the economy of transformer construction, considerable effort is being made to increase that rise. However, when relatively high temperatures are involved, and particularly when these temperatures do not reach steady-state values, the conventional test procedures are not accurate enough. Such conditions are encountered in testing certain dry-type transformers at rated load, or in making overload tests in oil-immersed apparatus.

Use of New Insulating Materials

In the design of dry-type transformers, increasing use is made of materials which will withstand higher temperatures than cellulose. Some of these materials are allowed to reach temperatures of as much as 200 degrees centigrade for continuous operation.[2]

Performance on Heavy Overloads

Heavy overloads present a similar problem for all types of transformers. Such overloads are permissible, because the thermal capacity of the copper, oil and other parts of the transformer causes a time lag between load changes and temperature changes. Consequently, a winding which is not at the temperature limit for continuous operation may be overloaded for a short time without exceeding that limit.[3] Furthermore, higher temperatures may be permitted for short times, than for longer times, with no greater loss of life of the insulation.[4,5] For these reasons, a transformer may be selected for a given location so that the anticipated peak load will exceed the rating, thus utilizing the inherent short-time overload capacity.[6] This is particularly true in transformers with internal circuit breakers, intended to permit the greatest utilization of overload capacity consistent with satisfactory transformer life.

Paper 48-290, recommended by the AIEE transformer committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted August 4, 1948; made available for printing September 17, 1948.

Typical Transformer Performance

To illustrate the nature of the quantities involved in testing at heavy overloads, consider the following data, obtained from tests on a small oil-insulated distribution transformer. Figure 1 illustrates the temperature variations which will occur if rated load is applied to a previously unexcited transformer, is continued until equilibrium is reached, and then is removed to allow a return to ambient temperature. The corresponding transients are plotted in Figure 2 for a heavy short-time overload of the same transformer, and are distinguished from those in Figure 1 by being interrupted long before the temperatures reach their equilibrium. It should be noted that the test results on Figure 2 and subsequent figures have been obtained solely to illustrate the considerations and methods presented in this paper, without regard to the effect of temperatures upon the transformer insulation.

Of particular interest in Figures 1 and 2 is the difference between copper and oil temperature; this quantity is independent of the ambient, and is determined essentially by the design of the winding only. The difference is often referred to as a "gradient," or as the average temperature rise of the copper above that of the oil. Since the word, gradient, is used commonly to indicate a rate of change of a potential, the temperature difference will in this paper be designated as a differential. Consequently, let

T = average rise in copper temperature above ambient at any time; degrees centigrade
θ = oil rise above ambient at any time; degrees centigrade
D = average copper differential at any time; degrees centigrade
T_F, θ_F, D_F = final or steady values of T, θ, and D; degrees centigrade

Figure 1. Temperature rises in a small, single-phase distribution transformer at 100 per cent load

t = time since the start of the test; minutes
t_θ, t_D = time constants of the oil rise and of the differential; minutes

If the transformer is at a uniform ambient temperature in the beginning of the heating period, no heat energy is supplied to the oil itself at that moment. For this reason, the initial rate of increase is zero in the oil rise, θ, in Figure 2. A finite θ appears only after the windings have started to dissipate heat into the oil. This θ reaches a maximum rate of increase when the relationship between the heat energies dissipated from the windings and from the oil is such that heat is stored in the oil at a maximum rate. For similar reasons, the initial slope of the cooling curve of θ is not the same as its maximum rate of drop, which is reached some time after shutdown.

In the normal-load test (Figure 1) the heating and cooling times up to those maximum slopes become so small, as compared with the total running time, that the initial slopes of the θ curve are identified by the corresponding maximum values. Even then the initial rates of increase or decrease are much more rapid for D than for θ, but although D lies above θ at the start of the heating cycle, it becomes much less at the end, that is, $D_F << \theta_F$. These conditions are indicated graphically on Figure 1 by the time constants t_θ and t_D of the θ and D curves, which are the times required for the heating curves to reach final values θ_F and D_F without heat dissipation, or which are the times permitting the cooling curves to return to zero at the shutdown rate of heat dissipation. In the illustration, Figure 1, t_θ is nearly 20 times t_D. Also, since θ_F is much greater than D_F, the value of θ_F becomes by far the larger component of T_F. If, therefore, θ_F is measured accurately, and if D_F is read less accurately, the error in T_F resulting from the error in D_F will be small.

At higher overloads, the foregoing conditions are reversed, because the power has to be shut off in the lower part of the heating cycle, that is, long before θ has reached its steady value, and when D is still much higher than θ. For example, in Figure 2, the low-voltage differential D at shutdown is 118 while the oil rise θ is only 24. Consequently, D should now be determined with a higher degree of accuracy than θ. In this connection, note the very rapid decrease in D after shutdown. Also, the rate of decrease differs greatly for the two windings, being 35 degrees centigrade per minute in the low-voltage winding, but only nine in the high-voltage winding, at the shutdown point. Thus any measurement of D, made after shutdown, is subject to a large correction which may be quite different for the two windings. In the case shown, the total copper rise T of the low-voltage winding decreases to less than 50 per cent of its value at shutdown in three minutes.

Furthermore, certain variations of the differential prior to shutdown are not measurable by ordinary test methods. For example, Figure 3 shows the result of an overload test in which the differential reaches a maximum before shutdown, and then decreases, although the copper and oil temperatures continue to rise. Such an effect, produced by increased cooling efficiency at higher temperatures, is of importance in making calculations based on test results.

Limitations of Conventional Test Procedures

According to AIEE and American Standard Association rules, three methods are available for the test of these winding temperatures.[7] In each method, the rise is determined by one or more measurements after shutdown, and the only difference between the three procedures is the nature of the correction applied to determine the rise at shutdown.

One method requires that a correction of one degree centigrade be added to the measured value, for each minute elapsed between the measurement and shutdown, and applies only up to seven watts per pound winding losses, because the initial slope of a cooling curve is equal to the dissipated losses divided by the thermal capacity of the coils,[8] and a slope of unity implies that the losses are approximately equal to the capacity, that is, to a value which lies usually between three and eight watt-minutes per degree centigrade per pound.

A second method, introduced for higher losses up to 30 watts per pound, uses as correction the product of these losses with a factor which depends on the time between test and shutdown.

A third method, recommended for losses above 30 watts per pound, requires

Figure 2. Temperature rises in a small, single-phase distribution transformer at 400 per cent load

the measurement of the lower part of a cooling curve by a series of readings whose extrapolation furnishes the temperature at shutdown. Where very rapid temperature changes are involved, such as those of the low-voltage differential shown in Figure 2, the timing and extrapolation of these readings may be subject to considerable error.

These methods furnish the copper temperature at the instant of shutdown only, and on this basis, the corresponding heating curve can be calculated with but a limited degree of accuracy, as shown in Figure 4, by comparison with a tested curve. Overload tests, however, are usually made to obtain basic data for the calculation of the temperatures existing under any load conditions, or of the temperature variations produced by a cycle of widely changing load. In either case, the variation of copper and oil temperatures throughout the loading cycle should be measured. Attempts have been made to do this by the above methods, that is by making repeated shutdowns for periods long enough to obtain a resistance measurement, or by repeating the test a number of times and by shutting down after various time periods.[9] These procedures, however, are laborious, and are subject to the limitations set forth before.

Various systems have been proposed for calculating the temperature variations at heavy overloads from the results obtained at several moderate continuous overloads. These methods are not very accurate, since small errors, made in the measurements, are multiplied manyfold in an extrapolation to heavy loads. Also, since the variation of temperature rises and time constants with load is quite complex,[5,9] the extrapolation is difficult unless simplifying assumptions are made which do not give reliable results. The methods may be used with a fair degree of accuracy only if the highest overload involved in the calculation is less than one and one-half times the highest overload at which tests were made.

Figure 3. Temperature rises in a small, 3-phase distribution transformer at 375 per cent load

Fairly accurate data may be obtained by the use of thermocouples, embedded at various locations in the windings, since thermocouple temperatures can be read while the transformer carries its a-c load; but this practice has several disadvantages. By the presence of these couples, the insulation level of the windings is usually reduced to such an extent that the coils cannot be used in normal service and must be scrapped after the test. Consequently, the procedure becomes uneconomical, except in the case of simple test coils or of transformer samples for large quantity production. The lowering of the insulation level may also prevent testing under normal excitation. For finding an accurate picture of a transient temperature distribution, a large number of readings must be taken in a short time. Since the presence of the couples alters the heat flow conditions in the windings, it may be impossible to make the number of couples large enough for obtaining a good average value of the temperature. Hence, the resistance test is preferable to the use of thermocouples when measuring average winding temperatures.

New Test Procedure

In order to include the advantages, experienced with the use of thermocouples in the resistance measurements, a new technique has been developed which, as shown in this paper, permits continuous factory tests of average copper temperatures throughout any load cycle. This technique does not require the use of specially made units or of unusual test equipment. The system may be applied to single and polyphase transformers, with or without excitation, and will, in many cases, measure the temperature rises in two or more windings simultaneously. The accuracy and application of the method are limited neither by the magnitude of the winding losses nor by the value of the coil resistance, and repeated tests show that entire heating and cooling curves are reproduced with a maximum discrepancy of two per cent at any point.

Since in relatively rare cases, as, for example, in the test of individual single-phase units without taps, it will not be readily possible to connect the transformer windings for a temperature test under load, the readings will have to be taken after shutdown in the usual manner.

Figure 4. Heating and cooling curves in a small, single-phase distribution transformer at 325 per cent load

(1) Total copper rise T
(2) Oil rise θ
(3) Differential D

First, therefore, an attempt will be described to improve the evaluation of temperature tests made after shutdown. These methods permit more accurate determination of the temperatures at shutdown and of the heating transients. The computations may be based on a cooling curve, or, if the apparent thermal capacity of copper is known, on a single test point. A reasonable accuracy is obtained up to 75 watts per pound copper losses. This value corresponds to an initial cooling rate of 10 to 20 degrees centigrade per minute, and may be exceeded at 300 to 350 per cent load.

The Evaluation of Temperature Readings Obtained After Shutdown

In the evaluation of resistance tests of average winding temperatures present after shutdown, distinguish between the two conditions: that either a cooling curve, that is a series of test points is taken; or that readings are obtained only once at the earliest possible moment. In either case, the winding temperature passes through a heating and cooling transient before reaching the test point, as shown in Figure 4 for the short-time overload of a small transformer. Consequently, the evaluation must be made in two steps. First the test results are extrapolated along the cooling curve back to the moment of shutdown. Then the differential at shutdown is extrapolated along the heating curve to a final value. This method will be explained for the example of short-time overload tests of oil-insulated, or of other liquid-filled transformers, where the procedure is most complex, so that it can be applied to any

other type of insulation, cooling medium, and load conditions. Consequently, introduce

T_s = starting temperature; degrees centigrade

$T_a = 234.5 + T_s$ = starting temperature above the level of zero copper resistance; degrees centigrade

T = average copper rise above T_s at any time; degrees centigrade

θ = oil rise above T_s at any time; degrees centigrade

T_0, θ_0, D_0, t_0 = values of T, θ, D, t at shutdown

D_F, T_F = fictitious final or steady values of D and T; degrees centigrade

ΔD = correction of D between shutdown and test; degrees centigrade

Δt = time after shutdown; minutes

t_h = heating-time constant of the copper, that is, the time in which D would reach D_F without heat dissipation; minutes

t_c = cooling-time constant of the copper, that is, the time in which D would return to zero at the shutdown rate of heat dissipation; minutes

W_s, W_F = initial and final specific copper losses; watts per pound

r_0 = initial decrease of D after shutdown; degrees centigrade per minute

k = apparent thermal capacity of copper; watt-minutes per degree centigrade per pound

No appreciable exchange of heat energy between the oil and the outside air will take place during short-time overloads so that a variation in ambient with time can be neglected. For this reason, the rises T and θ are referred to the starting temperature T_s rather than to the ambient, as above, assuming that all transformer parts will be at the same temperature at the beginning of the test. Furthermore, the calculations extend, according to Figure 4, only over relatively small sections of the heating and cooling curves so that the rate of heat dissipation from each winding can be considered to change proportionally to its differential D. Then its cooling curve is represented by[10]

$$D = D_0 e^{-t/t_c} \tag{1}$$

In the analysis of the corresponding heating curve, the change of copper losses with temperature must be considered too. Actually, the oil rise θ and the differential D both contribute to any increase in temperature so that the losses as well as D and T can assume their final values only when θ becomes steady. However, in order to describe the heating transient of D by a simple mathematical function, fictitious quantities are introduced for the final values D_F and T_F on the assumption that the oil rise θ would retain its shutdown value θ_0 if the run were to be continued beyond the time t_0, that is,

$$T_F = D_F + \theta_0 \tag{2}$$

In addition to this, let D pass through the actual shutdown point D_0, t_0, and reach D_F under the assumption that the copper losses depend only on D and not on θ. Then D is given, as shown in the Appendix, by the function

$$D/D_F = 1 - e^{-t/t_h} \tag{3}$$

plotted in Figure 5. This curve has the same initial slope and shutdown point as the actual heating transient. The intermediate calculated values lie in the example, Figure 4, up to seven per cent above the test results, but are conservative, and can, therefore, be used for finding the copper temperature for shorter shutdown times than allowed in the experiment.

In these calculations, an apparent value must be employed for a thermal capacity k, referred to the weight of the active copper, by adding the heat stored in the winding insulation to that in the bare conductor. Like the temperature distribution, this apparent amount of k varies during any transient heating cycle. Note further that the time constant of the copper, referred to as t_D in Figures 1 and 2, actually has different values t_h and t_c in the heating and cooling periods, due to an increase in the specific losses from W_s to W_F, and in the capacity k between the start and the end of the heating curve. The slight change of k will be neglected.

In the test, the readings are usually given in terms of T and θ, and

$$D = T - \theta \tag{4}$$

Assume also that the oil rise θ is measured by thermocouple for the complete heat run.

Evaluation of Cooling Curves

Under these conditions, evaluate first a measured cooling curve. Its test points can be extrapolated to the moment of shutdown by using a French curve. The shutdown value of D_0 thus obtained depends on the shape of the ruler as well as on the judgment of its operator. In order to reduce these influences, the test points D of the cooling curve will be dropped to D_x on its tangent line at the shutdown point, as shown in Figure 6, so that the extrapolation can be made with a straight edge.

For this purpose, combine the corrections to be made between D and D_0, and between D and D_x

$$\Delta D = D_0 - D \qquad \Delta D_x = D - D_x \tag{5}$$

with equation 1 of the cooling curve, and with the function of its tangent line

$$D_x = D_0(1 - \Delta t/t_c) \tag{6}$$

and find

$$\frac{\Delta D_x}{\Delta D} = \frac{e^{-\Delta t/t_c} - (1 - \Delta t/t_c)}{1 - e^{-\Delta t/t_c}} \tag{7}$$

which is plotted against $\Delta t/t_c$ in Figure 7.

In a numerical calculation, extrapolate the test points back to shutdown with a French curve, lay a tangent line at the shutdown point, and obtain a first approximation of D_0 and t_c. For the corresponding values $\Delta t/t_c$, read $\Delta D_x/\Delta D$ from Figure 7, and compute ΔD, ΔD_x, and D_x by equation 5. A straight line through these points D_x will furnish a second approximation for D_0 and t_c which may be used to repeat the procedure. The method converges quickly, and the second approximation usually gives satisfactory results. A numerical example is given in

Figure 5 (left). Functions for calculation of heating transients

Figure 6. Extrapolation of a cooling curve to the moment of shutdown by conversion into a straight line

Figure 7. Correction for converting an experimental cooling curve into a straight line

Figure 8. Extrapolation of a cooling curve of a small, single-phase distribution transformer at 325 per cent load

Figure 8 by an evaluation of the cooling curve, shown in Figure 3.

In the second step of evaluating a cooling curve, that is in the extrapolation of D_0 to D_F, combine

$$W_F = W_s\left(1+\frac{T_F}{T_a}\right) \tag{8}$$

with

$$t_h = \frac{k}{W_s} D_F \tag{9}$$

and

$$t_c = \frac{k}{W_F} D_F \tag{10}$$

to find

$$t_h = t_c\left(1+\frac{T_F}{T_a}\right) \tag{11}$$

For obtaining a first approximation of t_h, estimate the value of T_F, and use the amounts of t_c and D_0 found by extrapolation of the cooling curve. Introduce $t/t_h = t_0/t_h$ into Figure 5, and obtain $D_0/D_F = D/D_F$ and D_F. For the new value of T_F, computed by equation 2, repeat the calculation to find a second approximation for D_F. How quickly this procedure converges, will be shown by an extrapolation of the heating curve of D, Figure 3. For this purpose, note a starting temperature $T_s = 25.5$, or $T_a = 260$, a shut-off point $t_0 = 55.5$, $D_0 = 81.2$, $\theta_0 = 68.4$, $T_0 = 149.6$, and also $t_c = 9.1$, obtained from direct tests and from Figure 8. Assume, for example, $T_F = 160$, and compute $t_h = 14.7$, $t_0/t_h = 3.78$, $D_0/D_F = 0.980$, $D_F = 82.9$, and $T_F = 151.3$ by equation 10 and Figure 5. With this new quantity T_F, find a second approximation of $t_h = 14.2$, $t_0/t_h = 3.91$, $D_0/D_F = 0.983$, $D_F = 82.7$ and $T_F = 151.1$. These quantities furnish the capacity k at shutdown by equations 8 and 10, if the specific losses $W_s = 27.1$ are obtained from the coil design. Then compute $W_F = 41.2$, and $k = 4.53$.

Evaluation of a Single Test Point Obtained After Shutdown

When only one test point is taken after shutdown, extrapolate D, equation 4, to D_0 first for the condition of a Δt which is small as compared with t_c; that is, approximate the cooling curve of D by its tangent line at the shutdown point. For example, with a $\Delta t \leq 0.20\ t_c$, the discrepancy between the approximation and equation 1 will be less than ten per cent of the correction to be made. Under this condition, the shutdown slope of the cooling curve is represented by

$$r_0 = \frac{W_F}{k}\frac{D_0}{D_F} \tag{12}$$

where W_F is given by equation 7. For the evaluation, use an estimate for T_F and D_0/D_F, and compute k from the coil dimensions on the basis that the thermal capacity of active copper has a value of about three watt-minutes per degree centigrade per pound, and that the thermal capacity per unit volume of the winding insulation is approximately half as high as for copper.[11] Then k is found by introducing a winding space factor

$$S = \lambda\frac{\text{Active copper section}}{\text{Insulated coil section}} \tag{13}$$

The quantity λ represents an experience factor which has been found to lie, for example, between 0.80 and 1.00 for liquid-filled distribution transformers. Consequently, use

$$k = 3\frac{1+S}{2S} \tag{14}$$

in equation 12, compute

$$\Delta D = r\,\Delta t \tag{15}$$

and find D_0 by equation 5.

If Δt is not small as compared with t_c, that is, for example, with $\Delta t > 0.20\ t_c$, calculate t_c of equation 10 by finding D_F, W_F, and k in the same way as before, and obtain D_0 by equation 1.

From this point, the values of D_F and T_F can be extrapolated as in the evaluation of a cooling curve, but since the calculated value of k is independent of an estimate for D_F, obtain a shorter and explicit procedure by developing equations 3 and 9 into

$$D/D_F = 1 - e^{-t\frac{W_s}{kD}\frac{D}{D_F}} \tag{16}$$

Introduce an apparent time constant

$$t_a = \frac{k}{W_s} D \tag{17}$$

and find the function

$$t/t_a = -\frac{D_F}{D}\log\left(1-\frac{D}{D_F}\right) \tag{18}$$

which has been added to the chart, Figure 5, and which furnishes $D_F/D_0 = D_F/D$ for any given values of $t/t_a = t_0/t_a$.

For an example, use a single test point $T = 138.0$, $\theta = 69.5$, and $\Delta t = 1.47$ on the cooling curves of Figure 3, in addition to $T_s = 25.5$, $T_a = 260$, $t_0 = 55.5$, and $\theta_0 = 68.4$. Assume also that $W_s = 27.1$ and an approximate value of $k = 5.0$ are derived from the rating and dimensions of the winding. Estimate $D_0/D_F = 0.95$, $D_1 = 75.0$, that is, $T_F = 143.4$, and find, by equations 8, 12, 15, and 5, the values $W_F = 42.0$, $r_0 = 8.0$, $\Delta D = 11.8$ and $D_0 = 80.3$; or compute, by equations 10 and 1, the quantities $t_c = 8.9$, $D_0 = 80.8$, and $T_0 = 149.2$. Use the last amount of D_0 for D in equation 17, and obtain $t_a = 14.9$, whence $t/t_a = t_0/t_a = 3.72$. Then the chart Figure 5, furnishes $D_0/D_F = D/D_F = 0.972$, and $D_F = 83.1$, $T_F = 151.5$. Repeat the calculation with these values, and find, as a second approximation, $W_F = 42.9$, $r_0 = 8.35$, $\Delta D = 12.1$ and $D_0 = 80.6$; or $t_c = 9.7$, $D_0 = 79.8$, $t_a = 14.7$, $t_0/t_a = 3.77$, $D_0/D_F = 0.975$, $D_F = 81.8$, and $T_F = 150.2$, in close agreement with the first results.

The procedures just described for evaluation of temperature readings taken after shutdown improve the accuracy of the results obtainable by conventional methods. As indicated by the examples cited, however, these methods require rather laborious calculations, and still do not achieve a high degree of accuracy, particularly with regard to heating transients when high temperatures are involved. For this reason, the application of the procedure should be limited, as mentioned at the end of the description of conventional test procedures, to the

Figure 9. Circuits for a test of the high-voltage winding temperature in single-phase transformers under load, without line voltage

Figure 10. Circuits for a test of the high-voltage winding temperatures in three-phase transformers under load, without line voltage

Figure 11. Circuit for a simultaneous test of high-voltage and low-voltage winding temperatures in single-phase transformers under load, without line voltage

few cases to which the new technique of testing under load does not apply, because the test results become much more accurate, are much easier to evaluate, and may cover much more territory when using that new technique as explained by the following.

Temperature Tests Under Load

Most of the inherent errors and tedious computations, associated with indirect factory measurements of average coil temperatures, are eliminated, if these temperatures are tested while the transformer carries load, rather than after shutdown.

In this connection, it has already been pointed out that it is preferable to find these average temperatures from the corresponding change of the winding resistance. In order to make the method applicable, even when extremely high or extremely low coil resistances are involved, the principle of the Wheatstone or Kelvin bridge, employed for the conventional test of copper temperatures, is also used for making measurements under load; that is, direct current is supplied to the windings while they are under a-c excitation. Consequently, the d-c instruments and their operating personnel should be protected against the a-c voltage, and any alternating current entering these instruments must be reduced to an insignificant amount. Vice versa, the direct current sent into the windings should not enter the a-c supply circuits, since the resistance of these circuits would be included in the test results and would cause an error in the temperature readings. In order to comply with these requirements, the winding resistance is measured between points of substantially equal a-c potential, while the a-c excitation is supplied to terminals of practically equal d-c potential.

This a-c excitation of a transformer is known to consist of two components. One component is associated with the line voltage and core losses; the other component is identified with the load current and winding losses which cause the temperature rises to be measured. Note that the core losses are essentially independent of the load. Consequently, a core loss, for example, of 25 per cent of the total losses at rated load will amount to only about 2 per cent, at 400 per cent load, and will, therefore, have a negligible effect upon the temperatures. For this reason, the line voltage can be omitted in measurements at high overloads, and the load current is applied in a similar manner as in conventional short-circuit tests of winding losses.[12] Then, the a-c potential, to which the d-c circuit may be exposed, is reduced to a small fraction of the line voltage, and it becomes easier to protect the d-c instruments and their operators. At the same time, the connections for making measurements under load are considerably simplified.

Tests Without Applying Line Voltage

Figure 9 represents some typical examples of circuits without line voltage, and solves the problem of a temperature test under load for the high-voltage windings of single-phase transformers. In Figure 9(a), the low-voltage windings of two identical units are excited in series while their high-voltage windings are short-circuited in series. Then the high-voltage terminals a and b are at the same a-c potential, and can be connected to a d-c bridge which measures the two high-voltage winding resistances in parallel. An ordinary Wheatstone or Kelvin Bridge may be used for this purpose. The direct currents flow continuously during the whole temperature run, and must, therefore, be kept small enough not to contribute materially to the winding losses.

The same test can be made on a single unit with a connection shown in Figure 9(b). As found by experiment, the a-c voltage between any tap a and the common terminal b of a short-circuited winding is sufficiently small so that a d-c bridge can be connected to those two points. Then, the resistances of the two winding sections are tested in parallel. Tap a, therefore, should be located so that these two resistances become substantially alike, and the true average of the winding temperatures is obtained from the bridge readings. In the absence of any tap, an individual single-phase unit cannot readily be measured under load, but may be tested after shutdown, as described in the foregoing.

Because of manufacturing variations, and of lead and contact resistances, the alternating voltages and currents e and i at the winding terminals a and b are, even in the case of Figure 9(a), never zero, but are found to be of the same order as in Figure 9(b). This residual a-c excitation, supplied to the d-c bridge, can be characterized by the open-circuit voltage e appearing between a and b when the bridge is disconnected, and by the short-circuit current i flowing in a direct link between those terminals. In practice, values of open-circuit voltages e from 100 millivolts to 60 volts and of short-circuit currents i from 100 microamperes to 1 ampere, have been measured, depending

upon the rating of the winding under test. The actual amounts of e and i supplied to the bridge will be considerably smaller since the bridge resistances represent an a-c load at the terminals a and b of the transformer. For further reduction of this residual a-c excitation, a filter F, consisting of a variable capacitor and of an iron core reactor, can be inserted, as shown in Figures 9(a) and 9(b). If connected as in Figure 9(a), the reactor coil must be dimensioned to carry, during the whole temperature run, a direct current of perhaps several amperes which is supplied to the windings. In addition to this, the reactor resistance enters the test results like any invariable lead or contact resistance, and must, therefore, be kept small as compared with the winding resistance. A reactor complying with these requirements is about as big as the transformer to be tested.

The size of such a current-limiting device is considerably reduced by the connection in Figure 9(b), where it becomes practically independent of the unit to be tested. Note that a-c excitation does not disturb the d-c balance of a bridge, so that a residual alternating current may enter the bridge resistances, as long as they do not become overheated. Then, only the galvanometer G must be protected, and the reactor will be designed to carry at most a few milliamperes flowing through that galvanometer. Furthermore, this reactor is not in the winding circuit, and does not introduce an error into the measurements.

In many cases, satisfactory results will be obtained with such a reactor alone, or even without any current limiting device.

A protection against an excessive a-c voltage appearing at the bridge, due to wrong connections or winding failures, may be obtained by placing cutouts between terminals a and b, and between one terminal and ground. If the displacement current between the winding under test and ground can become appreciable, it may be advisable to replace the second cutout by a solid ground.

An application of the methods, introduced in Figure 9, to temperature tests of three-phase high-voltage windings under load, without line voltage, is presented by Figure 10. In the delta-delta connection, Figure 10(a), single-phase load current is circulated through the three low-voltage phases, while two high-voltage phases are connected and tested in the same way as in Figure 9(a). The third high-voltage phase is short-circuited separately. In the wye-wye connection, Figure 10(b), three-phase load currents are supplied to the low-voltage windings. The neutral a and the common short-circuit point b of the three high-voltage phases will be at the same a-c potential, and can, therefore, be connected to a d-c bridge which will measure the three winding resistances in parallel. In the delta-wye connection, Figure 10(c), the three low-voltage phases are excited in parallel by a single-phase load current, while the high-voltage side is connected and tested in the same way as in Figure 10(a).

If the temperatures of the high-voltage and low-voltage windings of a single-phase transformer are to be read in the same run, two units may be connected as shown in Figure 11. In this circuit, load current is supplied to the terminals p and q of a parallel connection of the low-voltage sides, while the high-voltage windings are short-circuited as in Figure 9(a). Then, not only the high-voltage terminals a and b, but also two low-voltage midtaps c and d will be at the same a-c potential, and are connected to separate bridges which are distinguished in Figure 11 as high-voltage and low-voltage bridges. The direct current in the low-voltage windings is divided between two parallel paths with d-c resistances of which the terminals p and q are the center points. Consequently, p and q are at the same d-c potential, as required.

Tests When Applying Line Voltage

These circuits must be modified considerably when the core losses cannot be neglected in comparison with the load losses, so that line voltage must be applied to the windings, as, for example, in the test at rated load of high-temperature dry-type transformers. Figure 12 shows a circuit for a simultaneous measurement of both sides of two single-phase units. The a-c line voltage is supplied to common terminals m and n of a parallel connection of the two high-voltage windings. Each low-voltage winding is divided into two sections with equal numbers of turns. The individual sections of the first unit are connected in series with the corresponding sections of the second unit. The two circuits, thus obtained, are connected in parallel, and load current is supplied through terminals p and q. Then, mid points c and d of these two low-voltage circuits, and midtaps a and b of the two high-voltage windings will be at equal a-c potentials for the d-c test. Note also that the same d-c potentials appear at the a-c supply terminals m and n, as well as at p and q, as required.

In another example, shown in Figure 13, the method of testing temperatures under load with line voltage is applied to the

Figure 12. Circuit for a simultaneous test of high-voltage and low-voltage winding temperatures in single-phase transformers under load and line voltage

Figure 13. Circuit for a test of the high-voltage winding temperatures in delta-delta connected 3-phase transformers under load and line voltage

Figure 14. Circuit for a simultaneous test of high-voltage and low-voltage winding temperatures in Y-delta connected 3-phase transformers under load without line voltage

high-voltage windings of two delta-delta connected three-phase units. Their low-voltage sides are excited in parallel by three-phase line voltage while single-phase load current is circulated in series through the windings. All high-voltage windings are connected in series in a closed circuit, so that the common terminals *a* and *b* of the two units are at equal a-c potential for the d-c test.

During these measurements under line voltage, the d-c bridges and their personnel may be protected against abnormal alternating currents and voltages in the same way as discussed in connection with Figure 9 for circuits without line voltage.

Test of Transformers Containing Circuit Breakers

Transformers containing circuit breakers present a special problem in temperature measurements at short-time overloads, because such loads are interrupted by these circuit breakers in order to prevent overheating of the windings. For insuring proper circuit breaker operation, the same current must flow through each circuit breaker in the test as under actual service conditions. If, for example, the breakers are normally placed in the low-voltage line leads of a delta-delta connected 3-phase transformer, single-phase load current should not be circulated through the windings, since such a current would by-pass the circuit breakers. Furthermore, in a test of several units, the load current has to be interrupted everywhere if the circuit breaker trips in one unit only.

A typical example of a circuit complying with these requirements is shown in Figure 14 for the simultaneous test of the high-voltage and low-voltage windings of two Y-delta connected 3-phase transformers without line voltage. These units are protected by circuit breakers placed in the low-voltage line. In order to let either circuit breaker interrupt the load currents of both units, they are loaded in cascade formation; that is, three-phase currents are supplied to the high-voltage side of unit *1* while the high-voltage terminals of unit *2* are short-circuited. Then the high-voltage windings of unit *2* can be tested in the same way as in Figure 10(b). On the low-voltage side, the corresponding line terminals of the two units are interconnected, and each delta circuit is opened to obtain points *c* and *d* of equal a-c potential, for the same kind of a d-c test as made on the high-voltage windings, Figure 13. Note also that two circuit breaker poles of each unit carry line currents, while only phase current passes through the third pole. This condition will insure proper breaker operation if the three circuit breaker contacts are mechanically interconnected, so that they will trip at the same time.

For a corresponding simultaneous test of two single-phase transformers with low-voltage circuit breakers, the low-voltage windings may be connected as shown in Figure 12, in order to insure interruption of all load current by the tripping of either.

Results of Temperature Tests Under Load

Examples of heating transients, obtained under load by the above methods, are found in Figures 1 to 4. In particular, Figures 1 to 3 contain temperature rises measured in some single-phase transformers, whereas Figure 4 shows the corresponding heating and cooling curves appearing at a short-time overload of a 3-phase unit.

Conclusions

The methods developed in this paper are useful tools with which a better picture of the thermal characteristics of transformers can be obtained. The accuracy represents a great improvement over the results furnished by conventional measurements since test values become reproducible with a maximum discrepancy of two per cent even when taking readings during rapid temperature changes. The constants and thermal capacities of windings may now be studied under load and under various heating and cooling conditions. Additional information may be obtained concerning the effect of short-time overloads upon the life expectancy of transformers. Furthermore, it becomes possible to check existing methods for calculating temperature transients with reliable test values so that these methods can be improved if necessary. The practice of obtaining resistance readings under load greatly reduces the effort required for an evaluation, and, consequently, is well suited for commercial applications.

$D_s < T_a$:
$(D/D_s)(1-D_s/T_a)$ against $(t/t_s)(1-D_s/T_a)$

$D_s = T_a$:
D/D_s against t/t_s

$D_s > T_a$:
$(D/D_s)(D_s/T_a-1)$ against $(t/t_s)(D_s/T_a-1)$

Appendix. Influence of a Loss Increase with Temperature upon the Thermal Transients of a Winding

Neglect any increase in losses with the oil rise θ, and introduce

L = winding losses at any moment t; watts
L_s, L_F = values of L at the start and at the end of the heating transient; watts
α = temperature coefficient of the winding resistance; 1/(degrees centigrade)
K = thermal capacitance of the winding; watt-minutes per degree centigrade

According to the principle of energy conservation, the heat balance in the winding will be, at any instant,

$$\text{Stored Heat} + \text{Dissipated Heat} = \text{Generated Losses} \quad (19)$$

Let the dissipated heat be proportional to the differential D, and note that all losses are dissipated from the winding at the steady end of the transient. Then, obtain in any small time interval δt, and for a corresponding small increment δD of D

$$\text{Stored Heat} = K\delta D$$

$$\text{Dissipated Heat} = L_F \frac{D}{D_F}\,\delta t$$

$$\text{Generated Losses} = L\delta t$$

and find

$$K\delta D + L_F \frac{D}{D_F}\delta t = L\delta t \quad (20)$$

By substituting

$$L = L_s(1+\alpha D) \quad (21)$$
$$L_F = L_s(1+\alpha D_F)$$

relation 20 can be transformed into the differential equation

$$K\frac{dD}{dt} + L_s\frac{D}{D_F} = L_s \quad (22)$$

in which the temperature coefficient α no longer appears. Note also that

$$\frac{L_s}{K} = \frac{W_s}{h} \quad (23)$$

and introduce the heating-time constant given in equation 9

$$t_h = \frac{k}{W_s} D_F$$

that is, the time in which D would reach D_F without heat dissipation. Then, equation 22 may be written

$$\frac{dD}{dt} + \frac{D}{t_h} = \frac{D_F}{t_h} \tag{24}$$

and has the solution previously given in equation 3

$$D = D_F(1 - \varepsilon^{-t/t_h})$$

Although this transient is derived for variable winding losses, it has the same form as for constant losses.[10] The only differences lie in the numerical values to be used for D_F and t_h. The quantity D_F depends solely on the losses at the end of the heating period while the value of t_h is determined also by the losses at the start, as shown by equation 9.

The general character of equation 3 can also be illustrated by introducing the quantities

D_s = steady value of D for $\alpha = 0$, that is, the value reached under the condition of winding losses L_s at the end of the heating transient; degrees centigrade

t_s = heating time constant for $\alpha = 0$, that is, the time required in which the heating transient would reach D_s without heat dissipation; minutes

Because of the proportionality between D and the dissipated heat, find, instead of equation 21,

$$\left.\begin{aligned} D_F &= D_s(1 + \alpha D_F) \\ D_F &= D_s/(1 - \alpha D_s) \end{aligned}\right\} \tag{25}$$

Write further

$$\alpha = 1/T_a \tag{26}$$

and

$$t_s = \frac{k}{W_s} D_s = t_h/(1 - D_s/T_a)$$

and introduce the equations 9 and 26 into equation 3 to derive

$$\left.\begin{aligned} &D = \frac{D_s}{1 - D_s/T_a}\left(1 - \varepsilon^{-\frac{t}{t_s}(1 - D_s/T_a)}\right) \\ &\text{for } D_s < T_a \\ &D = D_s \frac{t}{t_s} \\ &\text{or } D_s = T_a \\ &D = \frac{D_s}{D_s/T_a - 1}\left(\varepsilon^{+\frac{t}{t_s}(D_s/T_a - 1)} - 1\right) \\ &\text{for } D_s > T_a. \end{aligned}\right\} \tag{27}$$

As shown by relative values in Figure 15, the heating transient of D retains for variable winding losses its conventional form, Figure 5, only under the condition that the final differential D_s remains smaller than the starting temperature T_a above the level of zero losses. For $D_s = T_a$, however, the heating curve goes over into a straight line while for $D_s > T_a$, this chart obtains an exponential form with an opposite curvature as for $D_s < T_a$. Neither one of the last two transients reaches a finite steady value D_F, that is, the winding temperature increases indefinitely when D_s attains or exceeds a critical amount T_a. Such a condition may be reached in the operation of high temperature dry-type transformers.

Discussion

M. F. Beavers (General Electric Company, Pittsfield, Mass.): The desirability of a practical method of accurately and continuously measuring the winding resistances of a transformer for purposes of determining the winding temperature during heat run tests cannot be questioned.

To be practical, the method must employ equipment with reasonable proportions as to size and kilovolt-ampere ratings to be tested, must be safe for operating personnel, and be reasonable in cost of installation and upkeep. The authors indicate that the reactor employed in the filter in Figure 9(a) of the paper is physically about as large as the transformer being tested. This would seem to limit the application of this scheme to small transformers. The scheme shown in Figure 9(b) of the paper appears to be more suitable for large power transformers. It is not clear from the paper whether one of these schemes is more accurate or suitable than the other, but if they are comparable in all other respects it appears that the scheme in Figure 9(b) of the paper would be preferable from the standpoint of size of filter equipment alone.

Both of these schemes require that a midtap or connection be available in each winding to be measured when testing a single-phase unit. Such midwinding connections are seldom present in 2-winding transformers and are quite rare in 3-winding types. This requirement alone will usually make this method of resistance measurement unsuitable for tests on a single unit of a production design. However, if tests are to be made on two similar units, or on a development basis, midpoint taps may be provided for the purpose of the test.

If two or more windings are to be tested simultaneously, two or more d-c bridges will be required. Of course, one bridge may be used if suitable switching facilities are available and if it is not necessary to obtain simultaneous readings on all windings.

With regard to accuracy, the authors present but little evidence in the way of test data to substantiate the claim that their method is more accurate than present methods of making temperature tests. With this method, particular attention must be given to obtaining good connections to the winding terminals so as not to introduce errors due to poor contact resistance and to overheated connecting leads.

This method should be particularly useful in developmental work involving temperatures under transient heating and cooling conditions where present methods are not suitable for observing the temperature-time characteristics of windings under load conditions. As a substitute for the present methods of making commercial temperature tests (continuous rated load) it is believed that considerably more experience with the proposed method will be required before the method can be considered for making commercial acceptance tests.

The proposed method offers to the industry another tool in the search for better understanding of transformer thermal characteristics, and the authors are commended on their work as a step in this direction.

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): The authors have devoted considerable space to the derivation of a formula for calculating the cooling after shutdown. This formula has been given many times in the literature[1] and I used it for many years but abandoned it a few years ago. The reason I abandoned it is that it applies only when loss of heat is proportional to temperature rise under ultimate conditions. In practically all cases for oil-immersed windings, the loss is proportional to the temperature rise over oil, raised to an exponential power ranging from about 1.20 to approximately 1.43, depending on the conditions of cooling. Many tests have shown that under certain conditions the exponential power should be factored when calculating the cooling after shutdown.

The equation that applies was derived in an AIEE paper,[3] and is of the form

Figure 1. Temperature differentials in the windings of a small distribution transformer at 400 per cent load

$$\theta = \theta_0 \left[1 + (n-1)\frac{t}{B}\right]^{\frac{-1}{n-1}}$$

where

θ = temperature rise at any time "t"
θ_0 = initial temperature rise over oil at shutdown
n = exponent of ultimate temperature rise (θ^n) versus loss
B = time constant

The difference in results obtained by the two formulas is illustrated by the following example; assuming

$\theta_0 = 30$ degrees centigrade
$n = 1.25$
$B = 3$
$t = 4$ minutes

The cooling obtained by the formula given in the paper is 11 degrees, as against 12.3 degrees obtained by the foregoing formula.

The error is of course small for normal-load conditions but under heavy-overload conditions the error is too large to ignore.

In extrapolating cooling curves back to shutdown, I have found that the most convenient and most accurate method is to plot the increments of change in resistance versus time on semi-log paper. Resistance increments are plotted on the log scale and time on the linear scale. When the correct average oil temperature to which the winding is cooling is chosen, the test points all fall on a straight line. If the average oil temperature chosen is too high or too low, the test points will fall on a curve bending either downward or upward respectively. A little experience will soon enable one to easily extrapolate any cooling curve back to shutdown with a high degree of accuracy. This method is described and illustrated in Figure 27 of another article.[8]

Figure 2. Temperature distribution tested at shutdown in the high-voltage coil of a small distribution transformer at 400 per cent load

A. M. Lockie and G. M. Stein: The discussions by Beavers and Montsinger indicate that certain conditions described in the paper should be elaborated upon more in detail.

Beavers questions whether a reactor should be used for the protection of the bridge, as shown in Figure 9(a) or as in Figure 9(b) of the paper. The answer is that the reactor should be installed as in Figure 9(b), since then it can be much smaller than in Figure 9(a), but serves the same purpose. Furthermore, in Figure 9(b) the reactor becomes independent of the size of the unit to be measured so that the same choke may be used for the test of a small distribution transformer as for a large power transformer. If such a reactor is properly designed, that is, with a low power factor, the presence of such a reactor is practically without influence upon the accuracy of the test.

It has been conceded in the paper that, as Beavers points out again, two identical units or a single unit with a tap are required for a temperature test under load, and that the method does not apply to individual units without tap.

It is also of concern to Beavers that more than one bridge has to be used for the simultaneous test of several windings. The corresponding winding resistances are very frequently so much different in size that the measurements cannot be taken with the same bridge even in a test made after shutdown. Consequently, the use of several bridges in a temperature test under load will, in general, not constitute an increase of equipment over previous requirements.

If Beavers wants further evidence of an improvement in accuracy, he may note that a direct reading of the winding temperature at the moment of shutdown will supply this value necessarily with much higher accuracy than an extrapolation of measurements obtained only some time after shutdown. In addition to this, the new technique furnishes the whole average heating curve of the winding. As shown in Figure 3 of the paper and Figure 1 of the discussion, the differentials of such heating curves may contain maxima and turning points, a result which has never been found by the present method of making resistance measurements after shutdown only. In a repeat test of the condition (Figure 1 of the discussion), the whole transient temperature curve has been reproduced with an accuracy of ±2 per cent.

Furthermore, these resistance measurements of the high-voltage and low-voltage windings are compared, in Figure 1 of the discussion, with readings of thermocouples distributed in those coils. It is of importance that the transient differentials obtained with these thermocouples have the same peculiar shape as found by the resistance tests. From the high-voltage thermocouple readings (Figure 1 of the discussion) the temperature distribution in the high-voltage winding sections at the ends and under the iron has been derived, as shown in Figure 2 of the discussion for the moment of shutdown. The average of these two distributions agrees quite well with the average obtained by the resistance test.

Beavers stresses also the necessity of good bridge connections to the winding terminals. This requirement is not new or unusual, since it had to be observed to the same ex-

Figure 3. Analytic heating and cooling curves for different exponents of heat dissipation

tent in all previous resistance measurements of winding temperatures.

The new technique has been developed particularly for the test of the extraordinary high-winding temperatures occurring, for example, at heavy overloads of oil-filled units or in dry-type transformers with class *C* insulation. According to the introductory paragraphs of the paper, the technique is not intended to replace the present methods in commercial tests at continuous rated load of normal designs, as Beavers seems to believe, since for such tests the present methods can be considered as adequate.

In contradistinction to a statement made by Montsinger, formula 1 of the paper for representing a cooling curve has not been derived by the authors in their paper, but has been taken from the available literature. (See reference 10 of the paper). Montsinger objects to the use of this formula because it is based on a dissipated loss which is proportional to the temperature differential. He recommends, instead, a formula derived on the assumption that those dissipated losses vary in proportion to an nth power of the differential.

The authors themselves have used extensively Montsinger's formula for the cooling curve, and equivalent equations for the heating curve, in order to check the character of tested thermal transients. The equations for the heating curves are derived under the assumption that the resistance of the winding can be considered as being independent of the temperature, or that an average value L_a is used for the total winding losses in place of L_t and L_F, introduced in the appendix of the paper. If, in addition to this, the dissipated heat is represented by $L_a\left(\frac{D}{D_F}\right)^n \delta t$ instead $L_F\left(\frac{D}{D_F}\right)\delta t$, equation 22 of the paper will be modified into

$$k\frac{dD}{dt}+L_a\left(\frac{D}{D_F}\right)^n=L_a \tag{1}$$

and furnish, instead of equation 24 of the paper,

$$\frac{d(D/D_F)}{d(t/t_h)}+\left(\frac{D}{D_F}\right)^n=L_a \tag{2}$$

and

$$t/t_h=\int\frac{d(D/D_F)}{1-\left(\frac{D}{D_F}\right)^n} \tag{3}$$

This expression may be integrated for any value of n which is a rational number; obtain, for example,

$$\left.\begin{aligned}
&\text{for } n=1\\
&t/t_h=-\log\left(1-\frac{D}{D_F}\right)\\
&n=4/3\\
&t/t_h=\frac{3}{2}\left[\tanh^{-1}\left(\frac{D}{D_F}\right)^{1/3}-\tan^{-1}\left(\frac{D}{D_F}\right)^{1/3}\right]\\
&n=3/2\\
&t/t_h=\frac{1}{3}\log\frac{1-\left(\frac{D}{D_F}\right)^{1/3}}{\left(1-\sqrt{\frac{D}{D_F}}\right)^2}-\frac{2}{\sqrt{3}}\tan^{-1}\frac{\sqrt{3\frac{D}{D_F}}}{2+\sqrt{\frac{D}{D_F}}}\\
&n=2\\
&t/t_h=\tanh^{-1}\left(\frac{D}{D_F}\right)
\end{aligned}\right\} \tag{4}$$

The heating curves of D/D_F as functions of t/t_h, found by these equations, and the cooling curves of D/D_0 as functions of t/t_c, computed by Montsinger's formula, are shown in the Figure 3 of the discussion for several values of n.

By adding the test points of a number of ratings to such a chart, it has been found that the exponent n may vary widely between different designs as well as in each individual temperature-time curve, especially in a cooling curve; that is, the experimental transient may travel from one theoretical transient of a constant n to another. Such a departure of the test results from Montsinger's formula becomes especially pronounced if the measured differentials are not referred to the average oil temperature, but to the top oil temperature, like, for example, in commercial tests of self-cooled

Figure 4. Evaluation of test results of transient high-voltage-winding temperatures in a small three-phase distribution transformer at 350 per cent load

Figure 5 (left). Graphical evaluation of high-voltage heating and cooling curves measured in a small single-phase distribution transformer at 400 per cent load

Figure 6 (right). Graphical evaluation of initial high-voltage heating and cooling curves measured in a small distribution transformer at 600 per cent load

transformers, since the two oil temperatures do not change at the same rate with time. In the example, Figure 3 of the discussion, computed for the conditions of Figure 1 of the discussion, the tested differentials of the cooling curve lie in the neighborhood of $n = 1^1/_2$ when referred to the average oil temperature, but cross from $n = 1^1/_2$ to $n = 1$ when referred to the top oil temperature since these latter differentials have to become negative for sufficiently long times. The discrepancy between the corresponding analytical and tested heating curves in Figure 3 of the discussion, is not as big as that found for the cooling curves. In these heating transients, it also makes little difference whether the differentials are referred to the average oil or to the top oil temperature, except that the latter values cling more closely to the curve $n = 1$.

Very frequently, a whole heating transient can be approximated accurately by the theoretical curve for $n = 1$, as shown by the example given in Figure 4 of the discussion. In addition to this, the initial slope of all heating transients in Figure 3 of the discussion is the same, and so is the initial slope of all cooling transients. These slopes are independent of n since they represent the condition that no heat is dissipated. Up to the time values of $t/t_h = t/t_c \approx 0.4$, the heating and cooling curves, Figure 3 of the discussion, run sufficiently close together so that, practically, it will not make any difference what value of n is used to interpret the test results. Consequently, the functions obtained for $n = 1$, which are the simplest ones, will serve this purpose. On the other hand, the test results of those initial portions of the heating and cooling curves constitute, for example, sufficient information for an extrapolation back to shutdown and for computing the thermal capacitance and the cooling-time constant of the winding.

For all these reasons, the authors have abandoned for some time all efforts to use a heat dissipation exponent other than $n = 1$, when evaluating heating or cooling curves. Montsinger seems to have come to a similar conclusion, since he recommends the extrapolation of cooling curves by plotting them on semilogarithmic paper. In such a coordinate system, the test curves of the differentials appear as straight lines only if they can be represented by equation 1 of the paper, which is Montsinger's formula for $n = 1$.

This method suggested by Montsinger will give more satisfactory results if the following modifications are introduced:

Instead of plotting resistance increments corresponding to temperature differentials which are the winding rise over an average of the oil temperature with respect to time, plot the temperature differentials, D, which are the winding rise over the actual variable oil temperature. Since the oil rise, θ, can easily be read by the use of thermocouples during the entire cooling period under consideration, there is no need to rely on an average value of θ only. Extrapolate the values of D on the semilogarithmic paper back to D_0 at shutdown, and lay a tangent to this experimental curve at the point D_0, as shown in Figure 5 of the discussion, for the example already introduced in Figures 1 and 3 of the discussion. The time Δt at which the ordinate D of that tangent line becomes equal to $D_0/(e = 2.71)$, is the cooling-time constant t_c. Then proceed to find the values of D_F, t_h, and k, as shown in connection with equations 8 to 11 of the paper.

In order to improve the accuracy of this method, take as many readings as possible within a time which is only a small fraction of t_c. This procedure is illustrated by the example, Figure 6 of the discussion, where a time $\Delta t = t_c/6$ is reached when D has dropped to $D_0/e^{1/6}$.

The problem of evaluating transient heating curves is somewhat different from that of analyzing cooling curves. In overload tests, the power is frequently interrupted before the differential reaches its steady value D_F in order not to overheat the windings. Actually, because of the increase of the losses with temperature, such steady differentials are obtained only when the oil rise becomes steady too. It is often impossible to continue the load that long without destroying the unit. On the other hand, the upper part of a heating curve, of the type shown in Figure 1 of the discussion, does not represent a simple mathematical function, so that only the portion up to the neighborhood of the first maximum or turning point can be approximated by equation 3 of the paper. In any case, the quantity D_F represents a fictitious final differential, introduced in the paper solely for the mathematical analysis of the test values; that is, D_F does not appear among these values but has to be computed from them.

In general, it is desirable to evaluate the tested curves in such a way that the results can be used to precalculate the heating transients for other load conditions. For this purpose, find not only the final differential D_F, but also the time constant t_h and the initial slope (in degrees centigrade per minute)

$$r_s = \frac{D_F}{t_h} \tag{5}$$

of the heating transient. The slope r_s will be of interest since it furnishes the thermal capacity, k, according to equation 9 of the paper in the form

$$k = \frac{W_x}{r_s} \tag{6}$$

If a good estimate for t_h can be obtained by plotting the whole test curve, the value of r_s may be computed by transforming the test points D into a straight line with points D_x, as shown in Figure 4 of the discussion. The procedure is the same as derived in the paper for the evaluation of cooling curves, if the temperature drop ΔD, and the time after shutdown Δt, are replaced by D and t in formula 7 of the paper and in Figure 7 of the paper. The quantity $\Delta D_x = D_x - D$ will then again represent the correction between the actual curve and the straight line points. Note how closely the converted test values at the start of the heating and cooling curves are approximated by straight lines so that the use of a heat dissipation exponent $n = 1$ appears quite justified in this example.

From these lines, the values of $k = 5.93$ and 5.65 have been computed according to the equations 8 to 11 of the paper and equation 5 of the discussion for the beginning and for the end of the heating cycle.

In order to reduce the numerical work in the analysis of tested heating transients, a second method has been developed in which these curves are approximated by equation 3 of the paper so that two test points D_1, t_1 and D_2, t_2 coincide with this mathematical curve, as shown schematically in Figure 7 of the discussion. This approximation is even better than the conversion into a straight line, since the upper part of the transient is included. For the analysis, introduce the ratio

$$a = t_2/t_1 \tag{7}$$

Figure 7 (left). Schematic diagram of the evaluation of heating transients by using two test points

Figure 8 (right). Chart for the evaluation of heating transients by using two test points

and find, according to equation 3 of the paper,

$$\frac{D_2}{D_1} = \frac{1-e^{-a\frac{t_1}{t_h}}}{1-e^{-t_1/t_h}} \tag{8}$$

The values of D_2/D_1 can be computed by this equation for any given amounts of a and t_1/t_h. In this way, t_1/t_h has been found as a function of D_2/D_1, and is plotted in Figure 8 of the discussion for the constant ratios of $a=0.1$, 0.2, 0.3, 0.4, and 0.5. In order to find the constants t_h and D_F by the help of this graph, select two values t_1 and t_2 of a preferably low ratio a. For the corresponding test values D_1 and D_2 and for their ratio D_2/D_1, take t_1/t_h from Figure 8 of the discussion and find t_h. For $t/t_h=t_1/t_h$, a quantity D/D_F can be taken from Figure 5 of the paper, furnishing D_F.

As an example, consider the transient heating curve of Figure 1 of the discussion, and select $t_1=26$ and $D_1=103.5$ at the turning point. Choose $a=0.1$, and find $t_2=2.6$, $D_2=21.4$, that is, $D_2/D_1=0.207$, which furnishes $t_1/t_h=1.96$ in Figure 8 of the discussion, and so $D_1/D_F=0.857$ in Figure 5 of the paper. Consequently, obtain $t_h=13.3$, $D_F=121.0$.

Compute $r_s=9.1$, according to equation 5 of the discussion, and $W_s=41.0$ from the current density in the winding, and find $k=4.40$ by equation 6 of the discussion.

The accuracy of the constants D_F and t_h, which have been obtained in this way from the experimental heating curve, may be checked on the basis that the quantity D_F-D of a heating curve, given by equation 3 of the paper, has the same analytic form as the differential D of a cooling curve when represented by equation 1 of the paper. Consequently, the initial part of a tested heating curve will approximate a straight line and can be analysed in the same way as a cooling curve, if such a heating curve is plotted on semilogarithmic paper in terms of D_F-D against t. The heating curve of Figure 1 of the discussion has been added in this way to Figure 5 of the discussion. Lay an initial tangent line to this curve, and find $t=t_h=13.7$ where this line reaches $D_F-D=D_F/e$. Use this new value of t_h, that is, $t_1/t_h=1.90$, and find a better approximation $D_1/D_F=0.848$ and $D_F=122$ by the help of Figure 5 of the paper. If a higher accuracy is desired, read, as in Figure 6 of the discussion, a quantity $t=t_h/6$ at $D_F-D=D_F/e^{1/6}$ by securing a sufficient number of test points in the lowest part of the heating transient.

The examples presented above should give sufficient proof that it is satisfactory to base the evaluation of heating and cooling curves on a proportionality between the differentials and the losses in the winding, as considered in the paper. Consequently, it is not necessary to complicate the analysis of the test data by resorting to Montsinger's formula with an exponent of heat dissipation other than $n=1$.

In addition to this, the authors show also how the experimental results, obtained by a heat run under load, can be evaluated for future use, and that the values thus found are much more accurate than those furnished by other methods.

Experience with Transformer Impulse Failure Detection Methods

L. C. AICHER
MEMBER AIEE

COMMERCIAL impulse tests have been performed for some 16 years. During this period the tests have been conducted in various manners depending upon the rules in effect at the time. Periodically the rules are amended to incorporate improvements in the technique of testing. It is a purpose of this paper to show how excitation during an impulse test complicates the test and confuses the interpretation of results. Experiences with testing techniques that promise improvement are related.

Impulse Testing in General

It is interesting to review the prevalence of impulse testing as experienced by one manufacturer. The fact that a larger percentage of the transformers manufactured are now tested, Figure 1, is only a part of the story. When today's volume of production is considered, it means a manifold increase in number of units tested.

The very nature of impulse testing makes it a time-consuming operation. It is then not unrealistic to review impulse testing practice in search of suggestions that will save time. Another desire of equal importance is for methods that lessen the possibility of a failure going undetected. Much time is consumed checking suspicious oscillograms to make sure no failures go unnoticed.

Most everything has been done, consistent with the proved ability of the equipment, to simplify the test program. The American Standard C-57[1] has been newly amended to allow recently developed techniques.

Transformer failures during impulse test, arranged according to simplicity of detection, can be classified as follows:

1. Winding-to-ground involving major insulation.
2. Winding-to-winding.
3. Across relatively large portions of the winding but not involving ground.
4. Between coils.
5. Between coil face and taps.
6. Between turns.

As is stated in ASA Standard C-57,[1] "—one of the most important matters is the detection of failure." It is also stated that indications of insulation failure include: "noise within the transformer; presence of smoke; excessive current or drop in voltage in the excitation circuit as indicated by the magnetic oscillograph; failure of a gap or bushing to flashover although the oscillogram indicates a chopped wave; and presence of oscillations or other variations from the expected wave shape as indicated by cathode-ray oscillograms."

A discussion of the individual indicators listed has appeared elsewhere in other literature.[2] Experience has shown that the presence of any of these is nearly positive proof of failure. However, it is insufficient to say that their absence is proof there has been no failure.

Improvements in impulse testing technique develop more rapidly than do standards. A certain period of proving is necessary before standards are amended, yet it is difficult to gain wide experience with a new technique until it is permitted by the standards. Many of the oscillograms in this paper were obtained during tests on experimental units while others are from units given commercial impulse tests.

Tests with Excitation

Several manufacturers have advocated the elimination of excitation during impulse tests.[2,3,4] The argument is based upon experience obtained with the test from the inception of recognized testing rules.

It is not essential here to discuss the reasoning behind excitation. The important point is that it has failed to do its job. The record shows that current does not follow the impulse failure path except under special circumstances. Furthermore, the complications of the test necessitate conditions that confuse the interpretation of results.

If a failure is suspected while testing with excitation, it is an axiom to eliminate excitation, drop all the exciting equipment from the circuit, and concentrate on the winding under test. This eliminates all the protective devices from windings not being tested, as well as isolating gaps in the impulse generator circuit. A highly sensitive resistance-potential divider can then be used instead of a capacitance-potential divider that is more subject to extraneous oscillations. Only then is there reasonable assurance that the disturbance is confined to the transformer.

A simplified diagram illustrating the impulse generator circuit connected to a transformer which is to be excited during tests is shown in Figure 2. The components C_1, L_1, R_1, R_3, and C_2 represent the effective parameters in the impulse generator circuit during discharge. Capacitors C_3 and C_4 in series form a voltage divider for measurement of the applied surge. The rod gap used to produce a chopped wave is identified by *RG*. An insulating and voltage ratio transformer is necessary to provide the proper excitation voltage to the transformer under test and to act as a buffer to prevent dangerous surges from reaching the source of excitation. In order that excitation volt-

Paper 48-291, recommended by the AIEE transformer committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted July 26, 1948; made available for printing September 9, 1948.

L. C. AICHER is with the Allis-Chalmers Manufacturing Company, Milwaukee, Wis.

age does not flow through portions of the impulse generator, an isolating gap, *IG*, must be provided. A fuse, *F*, must be provided to interrupt the flow of excitation current into the generator after the impulse has crossed the isolating gap on its way to the transformer terminals.

For the moment, consider the circuit of Figure 2, but without the two lightning arresters shown connected to the transformers. If such a circuit is used during an impulse test, a bushing flashover on a winding other than the one being tested probably will occur. Such a disturbance is shown in Figure 3A, at approximately 19 microseconds, obtained while applying impulse voltage to the high-voltage line bushing during which a low-voltage line bushing flashed over. Figure 3A is interesting as a tap failure is indicated at about 2 microseconds. Imagine the difficulty of recognizing the existence of a failure had the time interval between the failure and the bushing flashover been nearly zero.

Three lightning arresters were applied to the excitation circuit and third winding and the oscillogram of Figure 3B was obtained. The oscillogram shows that the lightning arresters have operated to prevent the bushing from flashing over, thereby reducing the magnitude of the disturbance on the tail of the wave. However, it is evident that the identification of a failure has been complicated by the introduction of additional disturbance produced by the necessary lightning arresters. Additional illustrations of the effect of lightning arresters operating are shown in Figures 4, 5, and 6.

Proof that the disturbances observed in Figure 7A are due to the lightning arresters, can be developed by applying repetitive surges to the winding under test while voltage measurements are made on the terminals to which the lightning arresters are connected. The oscillograms of Figure 7 were obtained on the same transformer as those of Figure 6, with the exception that those of Figure 7 were measured with a resistance-potential divider directly connected to the transformer, instead of a capacitance-potential divider. This test arrangement involved two lightning arresters. The lightning arrester operations are reflected into the applied voltage wave, Figure 7A, one at about 10 microseconds and the other at about 37 microseconds. The time at which lightning arresters discharge when connected to unsurged windings is governed by the shape and magnitude of the induced voltage wave of that winding. Figure 7B is of the voltage wave obtained on the low-voltage winding with the surge applied to the high-voltage winding, and verifies that the lightning arrester operation occurring at approximately 37 microseconds in Figure 7A is the lightning arrester on the low-voltage terminal. In a similar manner Figure 7C verifies that the disturbance at approximately 10 microseconds is due to the lightning arrester connected to the tertiary-voltage winding. The three oscillograms of Figure 7 are unusually consistent as to time of lightning arrester discharge.

Figure 8 shows four oscillograms obtained with successive applications of voltage upon a transformer. Note the variation in time to discharge as well as magnitude of disturbance produced by the lightning arresters. These oscillograms were obtained on the low-voltage winding of the transformer which produced Figures 6 and 7. Here the lightning arresters were in the high-voltage and tertiary-voltage circuit. No excitation was applied.

Upon closing the excitation circuit, a change takes place in the impedance of the load on the impulse generator such as usually to shorten the tail of the applied impulse wave. This is illustrated in Figure 9 which again is on the same transformer as Figure 8 with the addition of excitation. It is evident that the change in slope of the tail of the wave as compared with that of the reduced voltage full wave without excitation, Figure 8A, can lead to confusion during the demonstration that the transformer has withstood the test. A change in the slope of the tail of the wave could lead to an interpretation of high leakage over insulation to ground, or a change in the amount of winding that is in series with the impulse generator circuit.

Consider Figure 7C for a moment. If the applied voltage is increased the voltage induced in the other windings will increase proportionately. At the times of interest, the volt-time characteristic of the lightning arrester is flat and constant, plus or minus the manufacturing tolerances. When the applied voltage is increased from the reduced full wave level to full wave level, the time to lightning arrester operation is shortened for a voltage wave similar to Figure 7C. Since the lightning arrester discharge has occurred sooner, the reduction in length of wave tail starts earlier and results in a shorter tail than that of the reduced full wave.

Sometimes the time to a given lightning arrester operation can be controlled by adjusting the size of the lightning arrester in proportion to the magnitude of the applied voltage wave. For example if a 120-kv lightning arrester was normal for a given winding then during the reduced full wave test, applied at about 60 per cent of the full wave voltage, a 72-kv lightning arrester would be used.

There seems to be no question that if the cathode-ray oscillograph is properly used it will detect any failure experienced to date. It is very important that the measuring circuit be as sensitive as it is

humanly possible to make it. Extraneous oscillations must be sufficiently small as not to affect the intrepretation of the results. They cannot be filtered out by devices inserted into the circuit for such devices will filter likewise similar minute disturbances which may be caused by turn-to-turn failures in the transformer.

The cathode-ray oscillograph has detected failures where the 60-cycle excitation that was present offered no evidence. There is no question that the oscillograph will detect a failure from the line end of the winding to ground as represented by Figure 10. An example which involves the failure of 10.2 per cent of the winding between coils somewhat removed from the line end is shown in Figure 11, (A) the reduced voltage full wave and (B) the full wave which followed two chopped waves.

The tap failure pointed out in Figure 3 was in a section of winding extending beyond the grounded point and was removed as far from the point of measurement as is possible, yet the cathode-ray oscillograph indicated the failure.

Probably the most difficult type of failure to detect is a turn-to-turn fault. Such failures are most likely to occur during the application of a steep-front impulse test. This is because of the increased magnitude of voltage applied and the fact that turn-to-turn insulation has very little additional inherent strength at short times. Even so, the cathode-ray oscillograph has indicated turn-to-turn failures involving less that 1/10 of 1 per cent of winding. Figure 12 is an example in which considerable difference is noted after the steep-front wave has chopped to zero. The inability to match the oscillations about the zero line when the oscillograms are superimposed is as indication of failure. It is also possible that failure can occur during the rising part of the steep wave test.

Tests Without Excitation

After some eight years of impulse testing with excitation, and finding that excitation only added complications to the test, some testing was carried out without excitation. Fewer lightning arresters or other protective devices were used to control the flashover of bushings on the windings other than the one being tested. This did not eliminate the disturbances produced by the protective devices but it did reduce their number and simplified the preliminaries to a test which further reduces the complications that arise when a failure is suspected.

It is undesirable to stress any winding not being tested, particularly one on which there is no measuring equipment. It is reasonable to consider methods which will protect these windings and at the same time not produce the disturbances associated with some protective devices. Upon eliminating excitation, practical use can be made of linear resistors as protective devices. In many instances, the winding not being tested can be short circuited and grounded. Obviously this protects the winding and prevents bushing flashover.

On first thought this would seem to be a most impractical method of test because it does not approach service conditions. An analysis of what takes place within a transformer during an impulse test will soon show that at the initial instant when maximum stresses are usually obtained between turns and from coil-to-coil near the line end of the winding, conditions with this connection are representative. After some interval of time during which surge flows through the winding, a finite value of inductance exists and the winding under test will oscillate at a frequency depending upon the natural period determined by the capacitance and inductance components of the winding. When the other windings are solidly connected to ground, a maximum voltage is developed from the winding under test to all other windings. This is true because the induced voltage in the other winding is held to a minimum, thereby increasing the differential of voltage between the winding under test and those nearer to ground potential. The midpoint of the other winding will not remain at ground potential, but will rise to values above ground and will oscillate at frequencies determined by the characteristics of the winding. When so tested the magnitude of the voltage will be less than when each winding receives its appropriate impulse test. Such a test procedure is used on development work and on those commercial units where it is applicable.

Frequently it is not possible to maintain the nominal 40 microsecond length of tail during an impulse test. An answer is to provide an impulse generator of suffi-

Figure 10. Line-end to ground failure during full wave

cient energy output to produce the wave shape. This solution, however, is not always practical. It is possible to supply so much energy into a fault that the disturbances do not show in the oscillogram. This suggests that less emphasis on the length of wave tail is in order in favor of more accurate measurements. If the unsurged windings are protected by a grounded short circuit between terminals, a short tail may result. The short tail of the applied wave can be raised somewhat by connecting a suitable resistance between the winding terminals instead of the solid short circuit. One terminal only is then grounded. In other cases, resistance between the grounded terminal of the winding under test and ground is a desirable aid in raising a short tail. There is no cure-all. Each situation depends on the characteristics of the transformer.

The length of the tail of the impulse test wave as specified in ASA C-57 is rather arbitrary and primarily so defined for standardization purposes. The standards recognize that conditions can exist under which the nominal length of tail cannot be obtained. The length of the tail of the applied impulse wave influences the voltage from the winding to ground at points removed from the line end. These voltages are not determined by the turns ratio of the point in question in the winding, but rather by the natural periods of oscillations in the winding. A point often overlooked is that if conditions are such as to produce a short tail during an impulse test the same low impedance will dissipate the energy of a field lightning stroke in a correspondingly rapid fashion.

Neutral Current Measurement

Since the cathode-ray oscillograph has proved to be a very dependable device when properly used, it is not surprising that additional uses of the device have been suggested for failure detection. A method of measuring the current at the grounded terminal of the winding under test was suggested as a means of failure detection.[2] The procedure is to insert a shunt between the terminal and ground and apply the voltage developed across the shunt to the plates of an oscillograph. A recording would be made at reduced full wave level and at full wave level. It is highly desirable that the potentiometer ratios be adjusted so the physical amplitude of the oscillograms is comparable then they can be superimposed and easily studied for differences. Usually these neutral current oscillograms will consist of many frequencies and a mismatch is indicative of a change in the transformer's impedance such as when a failure occurs. Small changes in impedance result in larger changes in the neutral current oscillograms than occur in the voltage oscillograms taken at the surged terminal.

Experience has shown that the characteristics of the shunt are important. Its resistance must be as small as possible yet it must produce a suitable voltage for deflection of the oscillograph trace. If the resistance of this shunt becomes too large it affects the balance of surge currents in the transformer and may even cause flashovers of the grounded bushing. It can materially change the magnitude of oscillations in the winding under test. This is undesirable.

Figure 11. Coil-to-coil failure involving 10.2 per cent of winding

(A) Reduced full wave. (B) Full wave. (C) Reduced neutral current. (D) Full neutral current

Figure 14. Neutral current oscillograms of a low voltage winding

(A) Reduced neutral current. (B) Full neutral current

The writer's initial experience with this neutral current measurement is a rather striking example of what can be expected from this test. Figure 13A is the reduced voltage full wave obtained prior to the application of the steep waves shown in Figure 12. It was recognized that the oscillograms of Figure 12 indicated failure during the steep wave test. This is borne out further by the inability of Figure 13B to match Figure 13A. Unfortunately the potential divider ratio for these full wave oscillograms was not adjusted so as to give more nearly equal deflection of the records for comparison purposes. Figure 13C is the current neutral measurement obtained when a reduced voltage full wave was applied and Figure 13D is the current neutral measurement obtained during the full wave test. It is quite obvious that these current measurements will not superimpose. As mentioned earlier this was a turn-to-turn failure involving

no more than 1/10 per cent of the winding. It is worthy of mention that not all neutral current waves are as slow to reach their crest as are Figures 13C and 13D. This is illustrated in the reduced current measurement and full current measurement of Figure 14. The current measurements of Figure 13 are from a high-voltage winding whereas those of Figure 14 are from the low-voltage winding of the same transformer.

Insufficient wall thickness of insulation in critical regions may not lead to a major failure during impulse tests, but, excessive corona can exist and if sufficient number of transients are applied failure probably would result. The oscillograms of Figure 15 strengthen the case for the neutral current measurement. Upon examination of Figures 15A and 15B, one with limited experience could easily say the transformer has satisfactorily passed the impulse test. The critic certainly would recognize the differences when shown Figures 15C and 15D, the reduced current wave and full current wave respectively. In this instance, as has been suggested, a portion of a live part directly connected to the line terminal to which the surge voltage was applied was deficient in insulation-wall thickness. Sufficient corona existed to mark the insulation although failure had not taken place.

After the test which produced the series of oscillograms of Figure 15, two questions were raised, "Is not the current neutral method of failure detection too sensitive? Is it not a method of detection more sensitive than our ability to manufacture on a commercial scale?" An answer to these questions was obtained by testing typical major insulation barriers using a shunt between the test tank and ground. It was

(G) Neutral current oscillogram showing corona discharge but no failure

necessary to take a voltage wave then a current wave and continue this alternating arrangement throughout the test.

The impulse voltage on the barrier was raised to the maximum value possible before injurious discharges occurred. A voltage oscillogram of this wave is Figure 16A. The neutral current corresponding with the full wave oscillogram is in Figure 16B. A similar neutral current recorded with a faster sweep is illustrated in Figure 16C. Upon raising the voltage a small increment failure was produced as shown in the voltage oscillogram of Figure 16D. It is noted that a dip after the crest of the wave has occurred similar to those associated with the existence of corona discharge just prior to failure. The current neutral measurement corresponding with this failure is shown in Figure 16E which when expanded on a faster sweep is illustrated in Figures 16F and 16G. The conclusion drawn from this series of tests is that the current neutral method of measurement is no more sensitive than the voltage measurement, but is more positive because the magnitude of the recorded disturbance is greater. This is based upon the evidence shown here that both have indicated the existence of corona before breakdown.

An interesting example of the behavior of the current neutral measurement during a tap failure involving 9 per cent of the winding is shown in Figure 17. The taps were within a section of approximately 18 per cent of winding that was tapped out during the test. The failure occurred during steep wave tests. It was evident on the steep wave oscillograms, however, on the following chopped waves and full waves no evidence appeared on the oscillograms. Bubbles appeared following the full wave during which the current measurement was made.

Very often a failure in one winding will reflect itself into the oscillogram during tests on another winding. Such a situation was studied using the current neutral method of measurement in an effort to observe its behavior under these conditions. The transformer studied was a 3-winding unit in which a turn-to-turn failure involving 0.85 per cent of the winding existed in the tertiary winding. There is a slight difference between the reduced full wave and the final full wave as indicated by Figures 18A and 18B. Upon comparing the reduced current measurement 18C

Figure 17. Neutral current oscillograms showing tap failure involving 9 per cent of winding

(A) Reduced neutral current. (B) Full neutral current

Figure 18. Oscillograms of turn-to-turn failure involving 0.85 per cent of winding

(A) Reduced full wave. (B) Full wave. (C) Reduced neutral current. (D) Full neutral current

with the final current measurement 18D, considerable difference is noticed. These oscillograms were obtained during the application of the impulse voltage to the high-voltage line terminal. The current measurements were made at the high-voltage neutral. The oscillograms of Figure 19 were obtained by applying the impulse voltages to the line terminal of the high-voltage winding with the neutral solidly grounded but with the measuring shunt connected between, first the X_1 terminal and ground, Figures 19A and 19B, then the X_2 terminal and ground, Figures 19C and 19D. In each case the low-voltage winding was short circuited through the shunt and one terminal was grounded. A similar series of tests were conducted by applying surges to the high-voltage winding but measuring the current in the tertiary, first, on Y_1, Figures 20A and 20B then on Y_2, Figures 20C and 20D.

Whether the current neutral method of measurement will detect all failures in a winding obviously depends considerably upon the characteristics of the transformer. The magnitude of induced voltage in the various portions of the winding during tests on some other winding is controlled by the coupling between windings and will govern the effectiveness of measurements similar to those described in the previous paragraph. As a matter of fact, Figure 21 shows the current measurements obtained when the winding containing the failure was surged. Figures 21A and 21B are for the surge applied to

Figure 20. Neutral current measurements in windings other than the one surged. High voltage surged, tertiary voltage measured

the Y_1 end of the winding with the current neutral measurement made at the Y_2 terminal. A difference exists between these current measurements indicating failure as a probability. On the other hand, referring to Figures 21C and 21D, the current measurements obtained when the surge is applied to the Y_2 end with the measurements at the Y_1 terminal, no disturbance appears. In this instance, as pointed out previously the failure involved 0.85 per cent of the total winding and is located about 2 per cent of the winding from the Y_1 end. The results obtained are not an unreasonable situation for it must be remembered that during

gree of coupling between the various windings. The oscillograms were obtained by applying the impulse voltage to the transformer first to the X_1 terminal then to the X_2 terminal with the current measurement being made in the other terminal each time. No indication of failure is evident in either case.

Until now all of the discussion regarding the current neutral method of failure detection has indicated that it is a reasonably reliable method. But what about the other side of the story? The quantity of evidence that another and less desirable side of the story exists is not great. In fact the oscillograms in Figure 23 are the only oscillograms the writer is aware of which indicate the current neutral method may not always detect a failure. In this instance the oscillograms are arranged in the order in which the tests were applied. Two chopped waves were applied following the steep waves illustrated but since they were perfectly normal, add nothing to this discussion and have been omitted. The steep wave oscillograms, Figures 23C and 23D show a disturbance has taken place. Upon comparing oscillograms 23A and 23E it is difficult to find evidence of the disturbance. The current neutral oscillograms (B) and (F) can be superimposed with no indication of the disturbance. This is a conceivable situation assuming that the dielectric was of such strength as to almost withstand the steep wave test. It is further verification that the steep wave voltage levels are not coordinated perfectly with the $1^1/_2$ by 40 levels, otherwise a situation like this could not exist.

It should be pointed out that the experiences related here do not necessarily cover all types and designs of transformers. While several types are represented in the illustrations included in this paper it is possible that variations of these types can alter materially their response under transient conditions.

Conclusions

It is felt that while no one method of failure detection is infallable, the most desirable method is one making use of voltage oscillograms with neutral-current measurements. These tests would be made without excitation and without the addition of protective devices, except linear resistors to windings other than the one being tested unless such protective device is a permanent part of the apparatus.

For example, a by-pass lightning arrester applied to an autotransformer or feeder voltage regulator. The latest edition of ASA Standard C-57 suggests the use of the neutral current method of measurement. The standard has been amended to permit impulse tests without excitation. It is no violation of the standards therefore to conduct an impulse test in the manner suggested in this paper.

Discussion

P. L. Bellaschi (Consulting Engineer, Sharon, Pa.): We have barely completed the second revision of the Transformer Standards, ASA-C57,[1] when we find ourselves discussing a revision of the new standard. But this naturally is the course of modern standardization; a good standard is only a step to a better standard.

In the transformer test code, the section on impulse failure detection methods, no doubt, is an important one, for it has a bearing on the integrity of the transformer delivered to the user; it affects the test equipment involved; and, in fact, it influences the whole economy of testing, time consumed, and, believe it or not, the delivery date of the transformer tested. Therefore, it is proper that we take stock from time to time of the experience and developments in this field, as indicated in the paper.

One could very well take issue with some of the statements in the paper but for the purpose here we do know that the neutral-current method of detection, which consists in measuring the surge current at the neutral end or grounded terminal or in a separate winding, has shown distinctive merits and can well be considered seasoned by experience at this stage. In combination with the voltage oscillograms of the terminal tested, it permits looking into the winding from the two ends, so to speak, and with a much clearer view of what is going on inside.

To my knowledge, wherever the method has received a fair trial it has shown its intrinsic merits. According to my observations, even cases of secondary faults involving corona or minor discharges across a tap changer or similar effects, which might well have escaped detection by ordinary methods, have been picked up clearly by the neutral-current method. Judging from some of the minor disturbances detected, one might, perhaps, be tempted to the statement that the method is too sensitive. There have been a few cases, too, where reliance had to be placed entirely on the voltage oscillograph as well as the other usual observations. On the strength of present-day experience it would then be rather bold to claim infallibility for the method.

In a future revision of the Transformer Standards, the neutral-current method, no doubt, should be given greater prominence, but on general principles, it would be a mistake to exclude other possible useful methods. So far, acoustical methods have been tried out only to a limited extent; certainly, these too should be explored. How about chemical methods of detection? As a matter of fact, the attention given hereto to the neutral-current method has been almost entirely from the experimental approach. Very little has been done to analyze and rationalize the method.

A word or two in regard to international standards on transformers. These were discussed in a measure before the International Conference on High-Voltage, Electric Systems and meetings of the International Electrotechnical Commission held in Paris in the summer of 1948. In addition to attending these meetings, the writer had occasion to visit the various electrical manufacturers in Sweden and England, and also in Switzerland and Italy to find that impulse testing of transformers in a few of these countries has been making decided progress in recent years. For instance, a number of the 230-kv power transformers recently installed in Sweden have been impulse tested, practically at our levels, 1,025 kv. While the volume of power transformers tested abroad may not be as large as ours, rather intense research has been directed to the impulse failure detection methods. I feel quite confident that when it comes to deciding on an impulse test code for transformers in international standards, the neutral-current method of detection is due for a high vote.

In my opinion, the present transformer standards were drafted wisely. They permit testing by the neutral-current method. And in conclusion I would suggest that, due recognition be given to the neutral-current method in a future revision of the Transformer Standards, but that these be drafted not to impede future progress and developments. In the field of international standards, there is now reasonably good common ground for agreement on the matter of transformer impulse test methods.

F. J. Vogel (Illinois Institute of Technology Chicago, Ill.): The general subject of impulse testing for transformers is up for review. Aicher's paper is therefore both timely and good. There are several statements in the paper which I do not agree with, but also to enumerate them and discuss them would serve no useful purpose. I would like to point out some considerations which are now being taken into account by

a working group of the transformer committee regarding impulse testing.

It is felt that impulse testing is on the increase. I think that Aicher, and many other manufacturing and test engineers, would insist on such tests if they became responsible for purchasing or operating transformers. All manufacturers and test engineers agree that impulse testing with 60-cycle excitation has difficulties, and it would be desirable from this standpoint if such excitation were not required. The omission of 60-cycle excitation as a requirement has been proposed and probably will be recommended.

I feel that the detection problem is unduly accentuated. The use of oscillographs and choke coils for determining failures in insulation at 60 cycles is used for radio equipment but is not required for power transformers. Why not? Transformers were made for years to meet 60-cycle tests which punctured insulation and formed carbon paths, and still could be made that way so far as the standards are concerned. It is not necessary to change the standards because the specified tests alone determine the general level. Sixty-cycle excitation was in part required as it made impulse test conditions more similar to operating conditions and stresses from one winding were transmitted into other windings as in practice. However, these values might better be given up if the more general practice of impulse testing can be aided. Estimates of the loss in test severity on omitting 60-cycle excitation has been estimated to vary from practically nothing to around 14 per cent depending on the design and present levels. In the actual determination of failures, it is significant that the voltage oscillogram tells the story in almost every case. The author has seen several cases where failures occurred in other windings than the one being tested where the voltage oscillogram did not tell the story, and where 60 cycle follow did. Such cases are seldom, and if the impulse tests with voltage oscillograms only had caught 95 out of 100 cases of defective materials, workmanship, and design, I believe it would have been worthwhile. Even current neutral measurements would not have added greatly, since Aicher's paper indicates it is not necessarily more sensitive, but more apparent, and failed entirely in one case. Hence, the required use only of voltage oscillograms has been proposed.

Incidentally there is the converse point of view, several times expressed by our European contemporaries and sometimes heard here. It is that impulse testing is not desirable, because of the liability of undetected damage. I would like Aicher's opinion as to the reliability of the test. It is not possible probably to prove it, but tests of models and general development work has indicated to me that impulse tests are nearly perfect in detecting trouble and much better than 60-cycle testing. Further, I infer that a relatively large percentage of failures in commercial impulse testing practice has been experienced by some manufacturers, and I should think, from the nature of the failures, probably by all. Since impulse testing started and better protection has been afforded in service, very few service failures have occurred. This fact has been in itself used as an argument against impulse testing, inasmuch as many transformers which would have failed if they had been tested, are satisfactory in service. As I see it, this could be stated in this way by an operator or purchaser: If I have this unit impulse tested, I run a small chance of undetected damage, but a considerably larger chance exists that some defect will be found. A small percentage of the defects which are found might not cause service outage but some will. The present desire is for the greatest reliability possible. To obtain this, impulse tests should be made. To further bolster this argument, I know of several cases of failures where the units had not been impulse tested, but none where they had.

John V. Mulcahy (Bonneville Power Administration, Pittsburgh, Pa.): Aicher's excellent paper covering his experiences in impulse testing is a valuable contribution to this subject in that it not only outlines experiences over a considerable period of time, using several methods of failure detection, but gives specific examples of these experiences that demonstrate the advantages and disadvantages of the methods under discussion.

The general conclusions reached are:

1. With the transformers excited during the impulse test, many complications are introduced, particularly by the necessity of protecting windings not under test with lightning arresters or other protective devices, whose operation during the test may obscure failure indications on the oscillograms.

2. Neutral current measurements will give a more positive indication of failure, where failures occur, than the voltage oscillogram in nearly every case, even where excitation is not in the picture.

3. The most reliable test conditions are, therefore, to omit the excitation and include neutral current measurements in the general test procedure.

In the experience of the members of our group witnessing impulse tests on transformers at plants of most of the transformer manufacturers in the United States, for the Bonneville Power Administration, our observations agree with the foregoing conclusions.

Our experiences parallel those outlined in the paper even to the one example shown where the current wave did not show an existing failure. We have experienced at least two such instances.

In one such case a failure occurred, with the test applied to one terminal of a 34.5 kv delta winding, that was clearly indicated on the potential wave, but not so indicated on the current wave. Curiously enough another failure occurred when the test was applied to another terminal of the same winding and again this failure showed clearly on the potential wave, but on the current wave there was only a very slight possible indication. In this latter case the failure finally showed on the current oscillogram after two additional chopped waves were applied to the winding.

On the other hand, we have seen a test where without excitation on the transformer the indication on the potential wave (a very slight dropping of the tail) could only be identified after the current wave had clearly showed the failure.

The net conclusion that we have reached is that without the complication introduced by excitation, that with enough experience nearly every failure is detectable on the voltage wave, but that the confirmation attained by the current wave is an exceptionally valuable tool for use in the test. In this respect, I agree with Aicher that the current wave is not more sensitive, but is more positive in a great many instances.

All of this would tend to indicate that we believe the elimination of excitation from the test to be extremely advisable from a buyer's standpoint. This is not the case.

In Teague's discussion of this paper he pointed out that the addition of excitation during the test added stress to the winding, at some point beyond the line end, varying from 0 to 15 per cent. In my own calculation on various designs, I have found that this additional stress might be as high as 20 per cent.

It would seem to follow, therefore, that if additional stress is present then additional insulation margin is provided by the designer to withstand that stress. It would also seem to follow that if the designer knows that this additional stress will not be present during test, then he need not provide for it, unless his over-all margin is so small that he dare not take advantage of this situation. Of course, where the calculated excitation stress is small, as it is in some designs, then this would not be an important factor.

In any event, following the thought outlined before, the elimination of the excitation is a step in the direction of lowering the test standards.

This fact was recognized by Gross in his discussion of the paper, and suggested that perhaps the impulse test level be raised correspondingly. If this would be done, I believe that it would compensate satisfactorily for the reduced stress; but I am inclined to doubt that the manufacturers will be willing to increase the major test level within the respective insulation levels.

As an alternate suggestion, I believe a combination test would be in order. A way to achieve the desired results would be to apply the reduced potential and current waves without excitation, the chopped waves and potential full wave with excitation and the full value current wave without excitation. However, this would introduce an undesirable time factor between the last potential and current waves, so the same result may be achieved by using excitation during the chopped waves only. This might also introduce the undesirable time factor between the chopped and full waves, but this would need to be determined by experience.

I might mention at this point that as a matter of expediency, the Bonneville Power Administration transformer specifications have for some time permitted the option of testing with or without excitation if neutral current measurements are made. I should also mention that we do not use steep front tests, but only the standard full and chopped wave tests. Further studies may indicate the desirability of again revising this specification.

This step that indicates a lowering of the test standard is of some concern because there seems to be some feeling among the manufacturers that the standards should be lowered still further based on the fact that field failures are considerably less than factory failures on a percentage basis. This is further based on the fact that the tests, as applied in the factory, are much more severe than actual "service" conditions.

It is our present opinion that the dis-

crepancy between field and factory statistics may well indicate that basic insulation levels are too high, rather than test levels. The practice of ordering transformers with insulation levels one or more classes lower than the service on which they are going to be used, is already with us. If at the same time test levels should be lowered, before sufficient experience with the lower insulation levels is obtained, we are likely to be courting major operating difficulties that might reach disasterous proportions.

In his paper, the author refers to the fact that the excitation was provided to approach service conditions, but concludes that this is not essential.

At the present time there are opinions to the effect that chopped waves are too severe in factory tests because they exceed service conditions.

I rather deplore the use of the term "service conditions" when applied to factory tests. When equipment is tested in the factory, it is brand new in every respect. If the test applied then is of a severity only equal to service conditions, then what assurance does the user have that when the equipment has seen some years of service that it will continue to meet service conditions.

The test in the factory should be considered as a "norm" only; a standard to be met when the equipment is new that will insure the reliability of the equipment over its expected life. If the tests as now applied are too severe, then the manufacturer is justified in applying for relief; but only after it is definitely proved that the tests are too severe. If on the other hand, the situation is that the user has been buying too much insulation, he is justified in reducing his cost, but also be assured that what he has purchased is entirely reliable in all respects. Until this situation is definitely clarified, any step to lower test standards, even the small one of omitting excitation from impulse tests, is not justified, unless otherwise compensated for.

In summing up the foregoing observations, we agree that it is extremely desirable to eliminate during impulse testing all conditions that will tend to obscure faults that occur during test and to use the most modern methods for detecting failures. The manufacturers are to be congratulated for their zeal in developing impulse testing and failure detection methods to the high plane on which they now stand. At the same time it is undesirable to eliminate from the tests any condition tending to lower the standard of the tests whereby faults now uncovered by new detection methods are prevented from occurring only by virtue of a less severe test.

A. F. Rohlfs (General Electric Company, Pittsfield, Mass.): Aicher's objections to the application of 60-cycle excitation during commercial impulse tests are well founded. As a failure detection method it is undependable, and as Aicher points out, merely adds confusion to a much more reliable method, the cathode-ray oscillogram. Therefore, it seems logical that wherever possible 60-cycle excitation should be omitted so that the more refined method can be efficiently employed.

Aicher interprets the mismatching of the oscillations following "chop off" on the steep-front waves as an indication of failure. One must be very cautious in interpreting such discrepancies. The oscillations are determined by the various circuit loops to which the rod gap is common. Changes in the oscillations from one wave to another indicate that somehow the characteristics of at least one of these loops have changed, but this does not mean that the change must be in the transformer. Steep-front tests are accompanied by currents of the order of thousands of amperes with rates of change of ten thousands of amperes per microsecond. As a result, high voltage gradients are set up along the circuit leads, comprising the grounding and high-voltage networks. The grounding network may be extensive since accurate steep-front measurements require a single good ground, at the transformer, while the lower end of the impulse generator is allowed to "ride up." Thus, high voltages appear between portions of the grounding network and building ground so that it is possible to develop corona discharges in the ground side of some of the circuit loops. Such corona discharges are generally erratic and will distort the oscillations following "chop off" in different ways on successive waves.

Another factor which influences these oscillations is the time at which "chop off" occurs. Tests made with chopped waves have shown that in order to have the oscillations match precisely, the "chop off" times of the waves must be the same. Likewise, it is highly probable that if the "chop off" times of the steep-front waves are not exactly consistent, variations in oscillations may result. Both of these factors must be considered and investigated before a decision of failure is reached.

The case which Aicher cites, wherein the neutral current method did not detect a failure which occurred on a steep-front wave, Figure 23, is perfectly plausible. However, unless other indicators, such as bubbles or noise, suggested failure, the evidence of the steep-front waves themselves seems too slight to draw a conclusion of failure. Certainly it would be more than difficult to reject a transformer on such evidence.

On the other hand, if failure did occur on the steep-front wave, the chances for it to recur on the chopped and full waves would be greatly improved if these waves were applied directly after the steep-front waves so that the failure had only a short time to "heal." Unfortunately, it generally requires many minutes to convert from the steep-front circuit to the chopped and full wave circuit so that the chances for healing are greater in this case then they are between the chopped waves and full waves where a reasonably short interval between the waves can be maintained.

The suggestion that idle windings (those not being tested) be short-circuited brings up two questions. First, the effective impedance of the transformer as viewed from the impulsed terminal will be reduced, thus increasing the current flowing through the impulsed winding. Any small current changes caused by a failure will be more difficult to see. In other words, the sensitivity of the neutral current method will be reduced much the same as the sensitivity of an ammeter is reduced by connecting a shunt across it. Second, the short-circuiting of the idle winding may decrease the voltage between the impulsed winding and idle winding, particularly where the ends of high-voltage and low-voltage windings are physically adjacent. The polarity of the transformer may be such that the end of the idle winding oscillates in opposite polarity to the applied impulse. In such a case then, short-circuiting the idle winding would reduce the voltages between windings.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The paper clearly points out the effect of 60-cycle excitation on failure detection with the attendant uncertainties introduced by protective equipment. It is also very gratifying that the author has used the neutral-current method with obviously good results. This method has been used in the General Electric test department for four years and it might be well at this time to relate some of our experience, as well as to point out precautions which are necessary to make this method successful. In the following discussion, it is understood that simultaneous 60-cycle excitation is omitted and that comparison of reduced full wave and final full wave is the criterion of failure.

1. Generally speaking, most failures occurring during impulse tests on power transformer sizes can be detected by irregularities in the voltage waves. However, from conversations and publications in the technical press, it is clear that such a comparison is a subjective method and depends on the degree of skill in observation of the testman. It is here that the neutral-current method is of value. While it is still a subjective method, the degree of departure of the current wave obtained after failure has occurred from the wave shape during reduced full wave test is many times greater than appears in the voltage waves. It becomes, therefore, much easier to recognize that failures have occurred and a greater degree of objectivity is attained.

2. There are cases, particularly in high-impedance windings, where failures across small portions of windings are definitely not shown by the voltage wave while the current wave will indicate them plainly. There are probably intermediate cases where the current wave is of great help in assisting in the detection of even rather serious failures as shown in Figure 1 of the discussion. In this case the voltage waves show very minor changes in wave shape, while the current waves leave no doubt that failure had occurred. The fault in this case was so severe that it was necessary to reduce the applied voltage to less than 50 per cent of the full wave to stop the winding from failing. The fault occurred across 3 per cent of the winding of a 5,000-kva 3-phase transformer.

3. Neither method—voltage or current oscillogram comparisons—is an absolute method unless the final full wave is applied to the transformer as rapidly as possible after the previous chopped wave, or, where used, the steep-front wave. This comes about because failures can heal themselves by

Figure 1

filling the broken-down space with new, clean oil, if given sufficient time. Since, in general, stresses occurring across small portions of a winding are much less during full wave application than for a chopped wave, a fault may not be detected, unless the full wave is immediately applied. This is one reason why failure detection during steep-front test is difficult because usually the impulse circuit must be changed which can take considerable time. At times this may be sufficiently long to seal off the fault with clean oil. I would suspect that this occurred in the case of Figure 23 of the paper.

4. Our experience shows that: if a 100 per cent voltage wave is applied rapidly (within a minute) after a chopped wave, it will indicate a previously established fault except in high-impedance windings. In all cases where the voltage wave will indicate a fault, the current wave gives a much greater indication, and is therefore, more sensitive. There were two cases, where a fault was indicated only by the current wave.

In our opinion, it is therefore essential that current waves be taken during impulse tests on transformers using the necessary precautions as outlined in the revised impulse test code of ASA Standard C57.2.

5. The short circuit of secondary or tertiary windings is attractive from a time-saving point of view. However, for the sake of fault detection, it is not advisable. By short-circuiting a whole winding, a short circuit comprising a fraction of a per cent of the impulsed winding, which constitutes a relatively high impedance, might not be recognized. The use of linear resistors to control the voltage on terminals not tested directly, as outlined in ASA Standard C57, 22.117 is therefore preferable.

W. L. Teague (Westinghouse Electric Corporation, Sharon, Pa.): Although great improvements have been made in the methods of impulse testing transformers, all who test in large numbers will agree that there is still a need for improved methods of detecting faults, and for simplifying and speeding up the tests. Aicher's experiences in detecting failures during impulse testing transformers are most interesting. He has presented some valuable information; but in our opinion has found more complication and confusion in excitation, and more virtue in neutral-current measurement as a means of detecting failures than is justified. Our experiences, based on association with the Westinghouse Laboratories since the beginning of impulse testing, leads to a different evaluation of excitation and neutral-current measurement.

When impulse tests were first standardized for transformers the aim was to reproduce in the laboratory, as near as possible, the same impulse-voltage conditions that exist in service. The transformer was to be excited at normal voltage and the impulse wave was to be applied on a crest of the excitation voltage of opposite polarity. There were two reasons for specifying excitation.

The first reason was to produce voltage-stress conditions in the winding similar to those in service. With the impulse synchronized to strike at the crest of the excitation wave of opposite polarity, the greatest change in voltage at the tested end of the winding will be experienced. The resulting voltage stress conditions in the winding will represent the worst that can be experienced in service. This contribution of excitation to the voltage stress conditions in the winding is a virtue of excitation that has not been mentioned in the paper. If a transformer does not have uniform voltage distribution the omission of excitation requires a sacrifice in stress between the turns and coils at the line end of the winding.

The second reason for excitation was a means of fault detection by magnetic oscillograms of the excitation current and voltage at the instant the surge strikes. In service the first evidence of a transformer failure from impulse voltages is power follow. If power did not follow impulse failures in service it would be a rather happy condition. We would have in our transformers the equivalent of automatic built-in lightning arresters. When impulse tests were first standardized it was reasoned that power would follow impulse failures in the laboratory the same as it does in service. This reasoning is sound provided all conditions are reproduced, but it is difficult to supply excitation circuits with recovery rates as in service. In our laboratory experience we have found that power usually follows impulse failures, but not always. When power does follow the magnetic oscillograms will show evidences of trouble. In a few cases, in our experience, the magnetic oscillograms were the only indication of failure. Usually, however, other evidences of faults are also present. In addition, where power follow is involved, excitation will aid in detecting faults by increasing the amount of smoke, bubbles, and noise.

Another advantage of excitation is that it aids in the location of the place of failure in the winding. In cases where power follows, even though it be very slight, it leaves a mark that is easier to locate on inspection than faults from impulse tests without excitation.

In evaluating excitation then it is a problem of balancing the advantages of the extra voltage stress conditions in the winding, and the aid in fault detection and fault location against the disadvantages of the extra complications, and the extra time required in making the tests. Our experience, based on a large number of tests with excitation, would lead us to conclude that excitation has served its purpose well. For development and verification tests we have found the advantages will justify the extra trouble and time. Since the ASA Standards now make excitation optional in commercial impulse testing, and since impulse testing has proved so valuable in detecting weaknesses and faults in windings; we have sacrificed the advantages of excitation on quality control test in order to speed up and streamline the tests so that more units can be tested.

Neutral current measurement as a method of detection consists of measuring the impulse current for a reduced full wave, and comparing this pattern current wave with that for the full-wave tests. If these two current waves are identical in form it is assumed that no failures have occurred.

Neutral current detection is applicable to full wave tests only. Current measurements have no value for any kind of chopped-wave tests. For detecting failures that may occur on front-of-wave or chopped-wave tests by this method, it is necessary to follow such tests by a full wave and to assume that any failures will reappear on the full-wave test and show irregularities in the current oscillogram. In our opinion this is not a reasonable assumption to make, since National Electrical Manufacturers Association (NEMA) steep-front waves are 30 to 70 per cent greater in magnitude and ASA chopped waves are 15 per cent greater than the full waves. Besides the two types of tests are intended primarily to stress different parts of the winding. Even though the full-wave tests are applied soon after the front-of-wave or chopped-wave tests, there is no assurance that the failure will reappear on the full-wave tests and be detected by the current oscillograms. This is a great weakness in the neutral-current method of detection.

Another limitation in the neutral-current method of detection is in the case of failures that may occur across a small percentage of the winding near the line end. In these cases the stresses result from the initial or capacitance voltage distribution, and remain across the part of the winding an exceedingly short time. Since the initial rush of current through the capacitance of the winding is high in magnitude, and usually oscillates violently, the first ten or more microseconds of the current wave may be so irregular as to make detection difficult and uncertain.

Our experience with the current method of detection leads to the conclusion that it is not a super-sensitive or a sure-shot positive method. It is just another method that also has weaknesses and limitations. Current measurement adds complications and requires more time in testing, since repeated tests must be made if one oscillograph is used. A better alternative would be to use an extra oscillograph or a 2-element oscillograph so that the current and the voltage oscillograms could be made simultaneously, but even this complicates the tests and requires extra time. In evaluating current measurement as a means of detecting faults we have not been able to justify its regular use in commercial impulse testing. In some types of failure, such as those in the interior or near the grounded end of the winding resulting from oscillations, it is a useful method. We use it when needed for investigating suspicious or questionable cases along with any or all other methods of detection.

Impulse testing has contributed so much to the improvement of the dielectric strength of transformers that every effort should be made to simplify and streamline the tests so that more and more units may be tested. Sacrifices to simplify and speed up the tests may well be justified. However, any additions tending toward complicating or increasing the time of impulse testing should be evaluated carefully.

H. H. Wagner (Pennsylvania Transformer Company, Canonsburg, Pa.): The author has presented some interesting data with rather significant implications and conclusions. Our own experience in commercial and laboratory impulse testing since 1932 confirms most of the conclusions in the paper with one or two exceptions.

We have found that normal frequency excitation during impulse tests serves no useful purpose, as power current follow rarely occurs, and also makes the detection of failures very difficult. In no case has a failure been detected by means of "power follow" using 60-cycle excitation.

Our use of neutral current measurement for over four years indicates that it is a very sensitive and fairly reliable method of failure detection. In fact, we have for the past $2^1/_2$ years taken neutral current oscillograms on all transformers which were given impulse tests.

With reference to Figures 12 and 23 in the paper, I believe it is doubtful whether

a failure is indicated conclusively in the oscillogram of a steep-front wave itself, without substantiation by subsequent full-wave tests. I do agree, however that it may be possible to have a failure during the application of the steep-front wave, and yet have no failure during the subsequent application of a $1^1/_2$ by 40 full wave. Although no AIEE or ASA standards have been established for steep-front wave testing, some commercial steep-front tests are occasionally being made which are probably not properly co-ordinated with the $1^1/_2$ by 40 wave levels.

L. C. Aicher: The variety of thought on this subject is very interesting. I am sure much good has been accomplished toward developing a better understanding of failure detection during impulse tests of transformers. It is regretted that some of the critics claim to take issue with statements in the paper, yet fail to make their thoughts known.

The intent in preparing this paper was to present an objective study of impulse failure detection methods. Individuals whose business involves witnessing impulse tests in the factory have expressed the need for such a study. They were particularly interested in a comparison of the relatively new neutral current method and the test with normal excitation. Certain other methods were not included because they are adequately discussed elsewhere.

Figure 23 of the paper has provoked considerable discussion. There is some feeling that because the neutral current method did not detect failure, in this instance, the method is of questionable value. Neither did the ASA Standard chopped waves or full wave detect the fault. As all who have had actual experience with impulse testing know, the phenomena displayed in Figure 23 is not uncommon. In a number of instances, steep wave tests have produced failures which have "healed" presumably by replacing old oil with new and then passed the recognized ASA test without incident. It is felt this criticism of the neutral current method is unjust because how can a method detect a failure when no failure occurred in the shots in question?

Hagenguth has very clearly summarized the outstanding characteristics of the neutral current method of failure detection.

Rohlfs indicates that a mismatch of the oscillations following "chop-off" on the steep-front waves may or may not indicate failure. As he points out one must be cautious in interpreting these discrepancies. His analysis of the many factors which can influence this portion of the oscillogram is correct. However, by proper arrangement of the high-voltage generator and meticulous care in the layout of the grounding network, much can be done to confine discrepancies to the transformer circuit. It is very important to compare steep wave oscillograms made under identical conditions. So little as lengthening the gap a fraction of an inch can produce discrepancies bearing no relation to the transformer. Our confidence in this method of detection has been bolstered by two experiences in which no other indication of fault existed. In each case the diagnosis proved to be correct.

Rohlfs and Hagenguth have raised a question regarding the wisdom of short circuiting those windings not being tested. This question has appeared before. An investigation was conducted using both the short circuited connection and an open circuit of the winding not under test. Aside from a noticeable change in the slope of the full wave the results were strikingly similar. The neutral current measurement possessed different frequency components but the existence of a known fault was equally noticeable in either. Subsequent experience has produced the interesting fact that the indication on the neutral current oscillogram can be greater in some cases, with the nonsurged windings short circuited.

A second criticism of this method of grounding the untested winding concerns the effect it may have on the voltage between the tested winding and idle winding. The claim has been made that such a connection decreases the voltage between these windings. The fact is it may also increase the voltage across the major insulation between the two windings. It is a matter of the polarity of the transformer, the arrangement of the windings and how the transformer is grounded for test.

Teague, Vogel and Mulcahy are unduly disturbed for fear the elimination of excitation during impulse tests will reduce the voltage stress conditions in the winding to undesirable levels. This reasoning seems to have entered the picture in recent years for it does not appear in the early writings regarding the reason for and use of excitation during impulse test. The early writings indicate that the principal benefit of excitation was for failure detection. An analytical approach to the joint use of excitation with impulse test indicates that under certain conditions an increase in stress could be expected. Efforts to confirm this solution have been most confusing. Some data indicates a slight increase, much with no change, some a decrease and still another set of data we have seen indicates an appreciable increase.

Before we become too distributed over the voltage stress question, let it be remembered that the steep-front wave test, to which Teague once referred, is from 30 to 70 per cent greater in magnitude than the ASA full waves, whereas, the change in stress which Vogel calculates is of the order of 14 per cent. As long as the steep-front test is used what is anyone worrying about? This test is already at a much higher level and produces stresses much greater than apparently can be produced if we accept that excitation does increase stresses.

Teague seems to feel that neutral current measurements have no value with any kind of chopped wave test. Certainly for chopped wave tests the characteristic of a neutral current measurement up to the time of chopping should be identical, except for magnitude, with that obtained on the full wave and reduced voltage wave. Since the chopped wave is at approximately 15 per cent higher voltage than the full wave, there is a good possibility that it will detect any faults which occur due to this higher voltage, up to the instant of chopping. This is demonstrated in Figure 16 where injurious corona prevailed just before the sample failed. As for indications after the wave has chopped experience is too limited to make conclusions. In general the same comment applies to steep-front tests where the neutral current has been measured. Experience indicates that with proper choice of oscillograph sweep (Figure 16) the early oscillations of the current neutral measurement do duplicate as long as no faults occur and conversely do not match when there are indications of faults.

It is difficult to agree with Mulcahy's conclusion that to eliminate excitation will permit a reduction in the insulation margin. If the analytical solution is accepted the greatest increase in stress would be near the surged terminal. As long as transformers are designed to meet the existing steep-front levels as well as the ASA impulse levels it is not possible to lower the insulation below present design practice. In many cases the design of the transformer is such that even the extreme stress indicated by the analytical approach is smaller than the margin necessary to cover manufacturing and material variation. Therefore, we cannot agree that the elimination of excitation is a step in the direction of lowering the standards.

There seems to be general agreement among all the critics of the desire to simplify the impulse test procedure. Some are willing to sacrifice what they believe to be a necessary test, if such a sacrifice furthers the cause without jeopardizing the product's reliability. With this in mind, the writer suggests that thought be directed toward substituting the NEMA front-of-wave impulse test for the present ASA chopped-wave test and follow with the present ASA full-wave test. Associated with this suggestion is one for a study of the possibility of adjusting the impulse generator so that it will be only necessary to change the charging voltage in order to change from a steep-front wave to a full-wave test. This may necessitate some modification in the tolerances or shape of the front of the full-wave test. If such a procedure can be followed it will permit considerable saving of time. There are very few transformers where the chopped-wave test dictates the design in preference to the steep-front test.

The writer is perfectly in accord with the practice of making standards cover general practices as far as test methods are concerned. The standards should cover all applicable methods. The writer would like to recommend, however, that the standards permit the group doing the testing to select which method it desires to use. Each testing facility has its own characteristic traits known best to the operators of that facility. Therefore, each testing group should be allowed to use the method that gives them the most satisfactory results.

Bellaschi's comments regarding European practice are interesting although somewhat at variance with the views of European engineers expressed in their technical journals.

It would be interesting to have additional thoughts on this subject from the users of the equipment.

Voltage Stresses in Distribution Transformers Due to Lightning Currents in Low-Voltage Circuits

K. D. BEARDSLEY

W. A. McMORRIS
MEMBER AIEE

H. C. STEWART
MEMBER AIEE

INFREQUENT reports of severe mechanical damage to small transformers as a result of nearby lightning strokes have led to the conclusion that the cause of the damage was the passage of heavy lightning currents through the two halves of the 3-wire low-voltage winding from the neutral to outgoing lines or the reverse. These cases have been rare, but are of considerable interest as they have led to the consideration of the effects of the more frequent lightning currents of smaller magnitude flowing through the same paths.

Considerable laboratory work done over a period of several years, supported by field investigations and service experience, has shown that relatively small currents entering the transformers by way of the low-voltage secondary service leads are the probable cause of an appreciable number of transformer lightning failures. They can result in the failure of insulation in either the primary winding or secondary winding, or both. The most probable point of failure is in the high-voltage primary winding. Lightning arresters connected to the high-voltage winding, although effective for surges coming from the high-voltage lines, are ineffective in controlling this type of damage because it can take place even with both high-voltage terminals solidly grounded.

Laboratory Tests

Studies have been made of the voltage stresses in distribution transformers when the low-voltage windings are subjected to impulses of varying lengths. Several connections of the high-voltage and low-voltage windings have been investigated. A comprehensive study also has been made of the effects of various physical arrangements of the windings. The most important result of this work is the discovery that destructive voltages may appear within a high-voltage winding due to lightning currents in the low-voltage windings, even though its terminals are both solidly grounded.

Four basic connections of the windings have been used in the laboratory study as illustrated in Figure 1. In the connection of Figure 1A, the impulse currents flow in the same direction in the two halves of the low voltage windings, and one high-voltage terminal is isolated. Conditions are the same in Figure 1B except that both high-voltage terminals are grounded. In Figure 1C, impulse currents flow in opposition in the two halves of the low-voltage winding, and one high-voltage terminal is isolated. The arrangement in Figure 1D is the same as for Figure 1C except that both high-voltage terminals are grounded. It appears that there are conditions under which damaging voltage stresses can be encountered with any one of these four circuits.

A previous paper[1] states that when an impulse voltage is applied to the high-voltage winding of a power transformer, the resulting voltages within the windings may be considered to consist of four components:

1. A voltage transmitted electrostatically to the low-voltage winding, depending upon the relation of distributed capacitances of the low-voltage winding to the high-voltage winding and ground and independent of the turn ratio.

2. A free oscillation in the high-voltage winding, consisting of a number of space harmonics, and which through its electromagnetic and electrostatic fields induces a corresponding oscillation in the low-voltage winding.

3. A free oscillation in the low-voltage winding, depending upon the distributed constants of the winding.

4. A unidirectional voltage surge transmitted to the low-voltage winding by electromagnetic induction, directly proportional to the turn ratio and independent of the distributed capacitance.

The same principles apply in the case of Figure 1A. Since the transformation is step-up instead of step-down, the four components described in the previous paper[1] have different relative importance. The electrostatic component which may put serious stresses on the low-voltage insulation of a high-voltage transformer becomes insignificant when the transfer is from low-voltage to high-voltage winding. Due to the few turns and small physical size of distribution-transformer low-voltage windings, the component which has to do with oscillations in the exciting winding also is of negligible importance. The two remaining components therefore are the ones to which attention should be directed. Natural oscillations of the high-voltage winding may be of importance, particularly as they affect internal stresses between layers or sections of high-voltage windings. It is well known that the electromagnetic component is sloped off by the effect of the leakage inductance between transformer coils. For this reason, for impulses of very short duration, the electromagnetic transfer may not result in large voltages. However, for impulses of greater duration, the voltage appearing at the isolated high-voltage terminal will approach that specified by turn ratio. In small distribution transformers, the turn-

ratio normally ranges between 20 to 1 and 110 to 1.

In Figure 1B the high-voltage winding is short circuited. In this case, the electromagnetic component cannot appear at the terminals, but tends to force oscillations within the winding.

In Figure 1C, the opposing impulse currents in the two halves of the low-voltage winding might be expected to cancel out so that there would be no net electromagnetic effect. In an actual transformer, however, individual turns of two windings cannot occupy identical locations, so that perfect current balance and flux cancellation do not exist. In fact, minor manufacturing variations in the positioning of low-voltage turns make surprising differences in the results obtained. One way of visualizing the phenomenon is to replace the low-voltage winding by a fictitious exciting winding with turns corresponding to the resultant unbalanced ampere-turns of the opposing coils. The very large turn ratio between the high-voltage winding and this fictitious winding explains the surprisingly large voltage which may appear at the high-voltage terminal.

When the terminals of the high-voltage winding are connected together, as in Figure 1D, oscillations are forced within it. In some cases the excitation not only may be large, but also of an asymmetrical pattern, so that high stresses will result in the high-voltage winding, not only between layers or sections, but also between portions of the winding and ground. Damaging stresses of this type are more apt to occur in transformers of the higher voltage ratings. This is due to the greater turn ratio and to the increased susceptibility toward internal oscillations of coils with many turns.

In order to understand the relationship between coil design and the type of stresses to be encountered with the various laboratory connections illustrated, many kinds of low-voltage and high-voltage winding construction have been studied. Investigations of flux fields were made by means of a search coil and vacuum tube voltmeter. Opposing current flux plots for two typical simple low-voltage coil arrangements are shown in Figure 2. Variations and combinations of these two types of flux plots were obtained for the different coil designs investigated. It is generally possible to predict the performance of a given coil arrangement by determining its flux pattern, resolving it into radial and axial components, and then estimating the performance under the various possible circuit conditions.

In order to set up test conditions in the laboratory which would simulate the most severe field conditions, a special low-voltage high-current impulse generator was built. By winding high-voltage coils with numerous taps, it was possible to measure with a cathode-ray oscillograph the voltage stresses between taps and from taps to ground. Figure 3 shows envelopes of oscillations measured for two typical distribution-transformer coil arrangements, tested with opposing low-voltage impulse currents and short-circuited high-voltage windings.

The oscillations encountered in a short-circuited high-voltage winding often are a combination of the two types shown in Figure 3. The second space harmonic, predominant in Figure 3A, is apparently a phenomenon related to natural internal frequencies dependent upon the physical dimensions of turns and layers. Tests show that this oscillation is affected very little by the energy in the applied impulse and the presence or absence of an iron core. The fundamental oscillation, predominant in Figure 3B, is reinforced by the presence of the transformer core. A copper shield between high-voltage and low-voltage windings, by means of eddy currents within the shield, tends to control the flux linking the high-voltage winding. As the shield thickness is increased, its effectiveness in cutting down the

Figure 2. Flux plots with currents flowing in opposite directions in the two halves of two typical low-voltage windings

Second space harmonic predominant — Fundamental predominant

Figure 3. Typical envelopes of oscillations in high-voltage windings (with both terminals solidly grounded) caused by impulse excitation of low-voltage windings

fundamental oscillation is, therefore, also increased.

In laboratory tests on typical distribution transformers, the response to applied impulses of short duration often is as shown in Figure 3A. As the length of the applied impulse is increased, the fundamental becomes more and more important, with little change in the second harmonic, so that the envelope of oscillations may finally approximate that shown in Figure 3B. For some types of high-voltage construction, the envelope approximates a sinusoidal rather than an angular envelope such as is shown in Figure 3B.

Considerable control of this type of voltage stress is possible by designing the coil arrangements with this phenomenon in mind. Practical designs have been evolved which reduce the magnitude of the fundamental oscillation to a low value. In general, however, there is a basic difficulty in designing transformer windings which are completely satisfactory for all possible conditions. For example, it frequently has been found in laboratory testing that a transformer which has relatively low stresses when connected as Figure 1D, may be severely stressed when connected as Figure 1C. In the field when opposing impulse currents flow through the windings, there is no assurance that they will be exactly equal in magnitude. Very small variations in winding or in coil alignment can result in abnormal performance. Extreme design measures which might be taken to minimize these effects under some conditions would be ineffective under other conditions, as well as economically impractical.

Field Studies

Several significant results have been obtained in the studies of this phenomenon that have been made in the field.

Tests have been made on a Y-connected rural distribution system to determine the relative number and severity of lightning surges on the secondary conductors. This was done by the use of surge crest ammeter links[2] which were installed on every conductor emanating from the transformer locations under study. The results as shown in Figure 4 indicate that the number and severity of the surge currents arriving at the transformers by way of the secondary leads or pole grounds were nearly as great as for those arriving by way of the primary leads. Figures 5 and 6 illustrate the current distribution in typical cases of surges arriving over secondary leads or pole grounds. Values entered opposite solid arrows are measured values of surge currents in crest amperes. Those entered opposite dotted arrows are estimated. The direction of the arrows indicates the direction of propagation of the surge and not its polarity.

It was recognized from the results of the laboratory studies that lightning surges entering the transformer by way of either the primary or secondary terminals could result in failure of primary insulation with no other damage to the transformer. Therefore, statistical studies of primary versus secondary insulation failures would not give a reliable indication of the relative severity of primary and secondary lightning surges.

Figure 5. Distribution of surge currents at a distribution transformer location

Surge arrived by way of secondary service conductors

Figure 6. Distribution of surge currents at a distribution transformer location

Surge arrived by way of pole grounds

Figure 4. Relative number and severity of measured surge currents on primary and secondary conductors at distribution transformer locations

It was evident that the best lightning protection to the transformer would be afforded by applying lightning arresters to the secondary as well as to the primary terminals. To evaluate the benefit derived from the secondary lightning arresters, lightning failure data were kept over a period of three years on two groups of distribution-transformer installations. Both groups were located on the same distribution system and, as far as could be determined, had the same degree of lightning exposure. The transformers and primary lightning arresters were the same in both groups. One group of transformers was equipped with secondary lightning arresters, and the other was not.

The type of lightning arresters used on the secondaries is shown in Figure 7. These lightning arresters are small and inexpensive. They are capable of discharging a 5 by 10 microsecond impulse current of 65,000 amperes. Their impulse sparkover is only 2 kv at 10 kv per microsecond, and their discharge voltage is only 2.5 kv while discharging a 10,000-ampere 10 by 20 microsecond impulse current. Two poles, each rated 175 volts alternating current, are housed in a cylindrical aluminum container only $2^3/_8$ inches in diameter by $2^1/_4$ inches long.

For each of the three years, the failure rate was consistently much lower for the group of transformers with secondary lightning arresters. Considering the entire period, the transformers with secondary lightning arresters had a failure rate of less than one-quarter that of the other group.

It should be appreciated that these results were obtained in a rather limited investigation involving only one distribution system. However, these results, together with the results of the laboratory studies, demonstrate conclusively that under certain operating conditions an appreciable number of lightning failures of distribution transformers can result from secondary impulse excitation. This phenomenon can be minimized to some extent by the design and arrangement of the transformer windings, but all winding arrangements commonly used are subject to some degree to this type of trouble. The most efficient distribution lightning arresters applied to the primary terminals are generally ineffective in preventing this type of damage, even to the insulation of the primary winding. The application of lightning arresters to both the primary and secondary terminals provides the most complete solution and can be justified economically if the lightning exposure of secondary circuits is severe or if a greater continuity of service is desired.

Conclusions

1. Laboratory tests show that lightning currents entering distribution transformers through the low-voltage secondary terminals can cause damaging voltages in the primary windings.

2. Lightning arresters connected to the primary terminals are generally ineffective in protecting the primary windings against voltages produced by lightning currents entering the transformer by way of the low-voltage secondary terminals.

3. A field study on a rural distribution system showed that surge currents arriving at distribution transformers over secondary leads or pole ground leads were nearly of the same frequency and severity as those arriving over primary leads.

4. Suitable lightning arresters are available for connection to the secondary terminals of distribution transformers for protection against secondary surges.

5. Comparative field tests on transformers with and without these secondary lightning arresters, in addition to the usual primary lightning arresters, showed that the secondary lightning arresters reduced the transformer failure rate to less than one-quarter the rate without secondary lightning arresters.

6. Installation of secondary lightning arresters at distribution-transformer locations is economical where secondary exposure is high or where a greater degree of continuity of service is desired.

Discussion

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The condition of surge voltages being transmitted to the high-voltage side of distribution transformers of sufficient value to cause failure of the high-voltage winding is particularly aggravated because of the disproportional insulation level of the two windings. In a transformer rated 7,200 volt, 120/240, the turn ratio is 60/30:1, while the insulation ratio from basic insulation impulse levels for the two voltage ratings is 75/30 or 2.5:1. It is, therefore, not necessary to transfer voltages from secondary to primary at a rate much in excess of 2.5:1 in order to exceed the insulation strength of the primary winding as compared with the theoretical possible transfer of 30:1 and more.

If secondary lightning arresters are used, not only is the voltage applied across the secondary terminals reduced, but in most cases the peak currents are shunted through the lightning arrester, by-passing the secondary winding. This also helps greatly to prevent the phenomenon of mechanical distortion of secondary windings.

As pointed out in the discussion of a previous paper[1], low ground resistances should materially assist in preventing current flow through the secondary windings by confining the lightning current to the point where a stroke occurs, either at the house or at the pole. While low ground resistance frequently is expensive to procure, a grounded and buried bare neutral conductor in the form of a counterpoise between the house and the transformer should assist materially in distributing lightning discharges directly into the ground rather than through the secondary winding, in those cases where it is difficult to get a reasonably low ground resistance by other means.

Electronic Speed Regulators for Sectional Paper Machine Drive

V. B. BAKER
ASSOCIATE AIEE

J. F. KOVALSKY
NONMEMBER AIEE

THE DRIVE for a paper forming machine is unique in that it must meet extremely rigid operating requirements not generally encountered on any other industrial machine. Control and regulation of the machine as a unit and of its components must be provided to a degree of refinement uncommon on machines of such huge proportions. The type and character of the loads vary widely. Continuity of service on a 24-hour a day 7-day a week basis is imperative.

Operation of the entire process from preparation of the raw material to finishing and shipping room activities are contingent upon uninterrupted production of paper from the paper forming machine. All processes leading up to the machine have multiple facilities, whereas the paper machine is a bottleneck and sets the pace for the entire mill. When the paper forming machine is down, it is not long before the whole mill is down. Hence, in addition to the requirements for the highest quality of performance, the drive equipment must also possess a reliability far greater than is required of the average electric drive.

Control for modern paper machine drives include industrial-type electronic devices that not only meet the stringent operating requirements, but also provide several important advantages over the control elements which they replace. Instantaneous response is inherent and extremely high amplification, where required, can be obtained without delicate mechanical adjustment. There are no moving or wearing parts. Initial adjustments are not subject to change over long operating periods. Optimum performance can be obtained with relatively low maintenance. These features are all an integral part of a new all-electronic speed regulator designed exclusively for paper machine drives.

A paper forming machine is essentially a combination of a number of machines each performing a special function in the complex process of forming a sheet of paper. On one type of machine, the sheet is initially formed on the Fourdrinier wire or couch section from stock consisting of $99^1/_2$ per cent water and 1/2 per cent cellulose fibres (pulp). When the sheet leaves the couch roll, sufficient water has been removed so that the sheet is self-supporting. It then passes through two or more presses where more water is removed. Next the dryers receive the sheet at approximately 60 per cent water and 40 per cent pulp by weight and remove all but 6 to 8 per cent of the moisture. The calenders then apply a finish to the dry sheet in a manner similar to ironing. The finished sheet is then wound into rolls on the reel section. In addition to these main sections, the paper machine may also include other special sections such as smoothing press, size press, or breaker stack as required for the production of different types of paper. A cylinder-type machine is similar to the Fourdrinier-type except for the forming end. On this type the sheet is formed on cylinder molds and carried through various auxiliary presses to the first main press on an endless wool felt. On machines designed for the production of creped tissues and toweling, all wet end sections including a large dryer roll known as a Yankee dryer are mechanically tied together and operate as a group. The dry end of the machine is operated at reduced speeds to provide the desired amount of crepe.

The operation of the various sections must be co-ordinated and their speeds synchronized to form a single continuous process However, the speeds of adjacent sections cannot bear a fixed relation but must be adjustable to meet the draw requirements for different types and grades of paper. Draw is the small difference in linear speed between adjacent sections usually resulting in a slight stretching of the sheet. Moreover, section speeds, when once set for a specific production run, must be held constant regardless of load changes or other system disturbances

Figure 2. Diagrammatic representation of the single generator type of sectional electric drive

Each of the all-electronic regulators in the cubicle at bottom center supply the excitation requirements of the individual section drive motors. A statically regulated master reference serves as a bench-mark to which section speeds are matched

in order to maintain uniform draws. Constant speed on each section of the machine under all conditions is essential to insure a high quality of product which can result only if the paper machine drive provides a uniform operating speed of the machine as a whole and accurately maintained draws between sections.

The two principal types of drives for paper machines are the mechanical or lineshaft drive and the sectional electric drive. The latter type consists of individual drive motors applied to each section of the machine requiring independent draw control. All sections of the machine must operate as independent units; the only mechanical link between sections is the sheet itself. Figure 1 shows a complete section drive unit including d-c motor and speed reducer both mounted on a common bedplate. Modern high-speed machines may have a total of more than 2,000 horsepower of applied motors with some individual sections having as much as a single 500-horsepower drive. Sectional electric drive has been applied to a large number of paper machines of all types. It provides improved operating practices, low maintenance, accurately maintained draws, requires a minimum of space about the machine, and permits the application of almost unlimited horsepowers per section without undue complication.

Present forms of sectional electric drive include the single generator system diagrammatically represented in Figure 2 and the multiple generator system as shown in Figure 3. In the single generator system, one generator supplies power to all of the section drive motors. A separate momentarily rated generator is included for starting and accelerating service, and for inching the various sections as required during operations such as felt or wire replacement and wash-up. The operating speed of the whole machine is controlled by adjusting the main generator voltage, and individual section speed is regulated by controlling the excitation of each section motor shunt field.

The multiple-generator system includes individual generators for each section motor and suitable control for each generator. Over-all machine speed is adjusted by changing a master reference voltage which is part of the speed regulating system. Section speed is regulated by controlling the excitation of the individual generators.

Some idea of the problems associated with the application of speed regulators to sectional paper machine drives is indicated by a review of a few of the more important operating requirements. Tests show that for some types of paper, section speeds on the dry end of the machine where the draws are most critical must be held within ± 0.05 per cent during normal operation. This accuracy is well within the limits wherein the sheet will neither sag down nor break. During transient disturbances, larger speed variations can be tolerated provided their durations are limited.

Moreover, the extreme accuracies required of the speed regulating equipment must be obtained even though the section load requirements and operating practices impose rather severe duty on the drive. Variations in vacuum conditions on the couch sections may cause swinging if the regulator does not possess the proper antihunting features. Changes in nip pressures at the press sections and doctor blade pressure on dryers and

* Per dryer roll

** Referred to the motor shaft

† Assuming 100 per cent torque available for acceleration

calenders produce load variations. Cascading of water in the steam-heated dryer rolls due to improper condensate evacuation causes erratic load swings on these sections. Calender frictions are far from constant. These undesirable conditions must be successfully handled on a machine whose physical makeup is far from ideal from the regulating standpoint. Table I includes data characteristic of a typical high-speed machine and indicates the extent to which horsepower, inertias, and time constants may vary throughout the machine.

The WR^2 of each section is the total inertia referred to the motor shaft. It will be noted that light inertia sections are located between high inertia sections. In addition, the length of sheet between the smoothing press and the first dryer is usually rather short. Considering the widely different mechanical time constants of these sections, it is apparent that, without modification of some sort, the problem of maintaining uniform draws would be extremely difficult. To ease this situation, flywheels of specified sizes are usually included on the drive equipment for light inertia sections which are located between or immediately adjacent to high inertia sections. In effect, the inertia characteristics of these light sections are made equivalent to the heavy sections. Thus, following a system disturbance, all of these sections will tend to respond in a similar manner. In determining the size of flywheel to produce this equivalence, both the section inertia and the electrical characteristics of the drive motor must be considered.

In the operation of the machine, the accelerating times of the various sections are important. On a machine producing light tissues, breaks quite often occur in the dryer sections necessitating their shutdown for clearing while the preceding portion of the machine is still producing paper. Thus, the maximum possible rates of acceleration and deceleration of the section are necessary in order that a minimum of lost production will result. Therefore, control for the drive must be arranged to utilize the section drives to the fullest extent of their ratings and at the same time impose a minimum of disturbance on the rest of the machine. Present designs of sectional electric drive include preset current-limit acceleration and deceleration.

On machines producing kraft paper, a very "tight draw" or high sheet tension is usually carried between the last dryer and the first calender. This is necessary in

Figure 3. Sketch showing layout of the multiple generator type of sectional electric drive

Each independent section of the machine is equipped with a complete set of drive components including drive motor, power supplying generator and totally enclosed control cubicle housing the all-electronic section speed regulator and the required sequencing relays and contactors. order to equalize the nonuniformities that may occur in sheet formation. In some cases the tension at this point may be so great that the drive on the first calender section actually pulls the last dryer section. On one machine producing heavy kraft board, the first calender drive actually assisted in driving not only the fourth dryer section but also a size press, the third dryer section, a breaker stack and, to some extent, the second dryer section. Thus, the dryer section drive may operate at practically no load and may even regenerate to full capacity of the drive. Under these conditions, if the sheet breaks between the calender and the dryer sections, a large block of load is thrown quite suddenly on the dryer-section drive. The drive must therefore pick up this load rapidly enough to prevent the accumulation of a loop known as sag-back between the last dryer and the preceding dryer or breaker stack. If sufficient loop is allowed to form, a wrinkle may occur as the sheet enters the dryer. Before this wrinkle has proceeded through the dryer, the operators, being unaware of the presence of a wrinkle, may have rethreaded the sheet into the calender. When the wrinkle reaches the calender, a cut will occur which almost invariably causes another break. This recurring sag-back condition can be prevented if the speed regulating system on the last dryer section is extremely fast and has sufficient forcing action to keep the initial sag in the sheet below a permissible maximum following a break.

Moreover, an unusually large loop may cause a wad or wrap in the dryer section necessitating a shut-down for cleaning. The lost production resulting from either a recurring break at the calender, a wad or a wrap in the dryer dictates a regulator design that is capable of responding under this severe operating condition. The all-electronic section speed regulator in combination with a booster generator is well able to meet these stringent operating requirements.

From a consideration of the foregoing, it is apparent that the speed regulators form an important part of modern paper machine drives. The new all-electronic regulator for sectional electric drive satisfies all of the widely different and in certain cases extremely difficult application requirements. It is capable of high accuracy, high speed of response, and is reliable and easy to maintain.

Regulation

Earlier designs of section regulators were primarily position regulators and employed some form of mechanical speed differential. Due to numerous moving and wearing parts, these drives all required strict adherence to a careful maintenance schedule in order to realize optimum performance. The all-electronic regulator as incorporated in one manufacturer's design eliminates the mechanical differential as well as all other moving and wearing parts of the former designs. Moreover, it provides all of the features of high sensitivity, quick response and effective antihunting essential to the proper operation of sectional paper machine drives.

After considerable analysis and actual field tests, it was determined that a high-accuracy speed regulator could meet the operating requirements. Such a speed regulator permits the use of a simple draw adjusting device consisting of a small potentiometer instead of a mechanical differential and cone pulley assembly as required with a position regulator. Quicker response can be obtained and a speed regulated system generally requires less complicated stabilizing elements.

Use of electronics in a high accuracy speed regulator for sectional electric drive was a natural outgrowth of many years of experience. The merits of electronic regulators for paper mill service have been demonstrated by the excellent service records compiled over long periods of operation as voltage regulators for sectional drive and speed regulators for single motor drives. Extremely quick response, the aim for simplicity of over-all design

Figure 5. Block diagram showing essential components of an individual section drive forming part of the single generator type of sectional electric drive

Current limit control of the starting generator voltage permits acceleration of the section drive smoothly and at the maximum permissible rate. The electronically-regulated running generator and constant voltage exciter busses insure constant over-all machine speed. The electronic regulator in the dotted rectangle maintains constant section motor speed by controlling motor shunt field excitation

and the availability of time-tested electronic components led to the development of an all-electronic system of section speed regulation.

Single Generator System

In this system, Figure 2, a single generator furnishes power to all section driving motor armatures. The regulators for all of the individual sections are located in a common cubicle similar to that shown in Figure 4. The paper machine speed range of say 6-to-1 is obtained by changing the armature voltage on all sections simultaneously by varying the running generator voltage. The speed changes resulting from necessary draw adjustments or variation in section load are obtained by motor field control provided in the electronic speed regulator. The complete section control includes the speed regulator, a speed indicating tachometer, magnetic control, and the operator's control station. Components which are common to all sections include electronic voltage regulators for the running generator and constant voltage exciter, master magnetic control, statically regulated master reference, and speed control for the over-all machine.

The a-c reference voltage regulator is a fully static device, unaffected by changes of voltage or frequency in the mill supply, and provides a master reference voltage to which the voltages proportional to speeds of all individual sections are matched. This master voltage is varied by means of a motor operated rheostat to provide the desired paper machine speed. The operating speed of this rheostat is adjusted to give a rate of acceleration commensurate with the section having the highest inertia.

Indication of section operating speed is obtained from an inductor type a-c tachometer generator directly driven from each section. This tachometer is usually driven from a high-speed shaft extension of the speed reducer as shown in Figure 1. Experience with d-c tachometers indicated that any d-c commutating device in the regulating system is undesirable because of the necessary frequent maintenance, variable brush drop, and the inability to isolate the long conduit runs from the section drive location to the regulator location. For these reasons, a rugged a-c tachometer generator was designed for indication of section operating speed.

Starting and inching of each section is obtained on the starting generator bus and during these operations, the electronic regulator supplies full field excitation to the section motors. The low initial voltage of the starting generator is automatically adjusted to meet the starting torque requirements of the individual section. When starting an individual section, the motor is connected to the starting generator and the excitation of this generator is then increased at a controlled rate to accelerate the section motor at the maximum permissible rate. A Rototrol regulator provides this current-limit accelerating feature. When the starting and the running generator voltages are equal, the electronic speed regulator then takes control, after which the section is transferred to the running generator with a minimum of disturbance to the system.

In the operation of a typical section speed regulator, a signal from the statically regulated master reference and a similar signal from the section tachometer are balanced against each other in an error detecting circuit as shown in Figure 5.

The difference or error voltage is amplified and used to control the 3-phase controlled rectifier which furnishes excitation to the motor shunt field. The circuit is so adjusted that the two signal voltages are balanced when the section is running at its normal operating speed. Under these conditions, the electronic exciter supplies the required excitation to the motor for normal speed.

The control station for each section is located on the tending side of the machine in a position convenient for the operator. It contains "start," "stop," and "inch" pushbuttons and draw adjusting rheostat as well as a load indicating ammeter. On the calender sections, "inch-reverse" and "slack-take-up" are also included.

A master control station provides for preset and manual paper machine speed adjustment, machine speed indication and a master stop pushbutton.

Figure 6. View of the master control cubicle as used in the multiple generator type of sectional drive

Included are a motor operated rheostat for machine speed adjustment, electronic voltage regulator for the constant voltage exciter, statically regulated master reference and other components common to all sections

Figure 7. Totally enclosed control cubicle for an individual section of a machine equipped with the multiple generator type of sectional drive

Adjusting resistors and sequencing magnetic control are located at the top above the all-electronic section speed regulator. Ample room and swinging panel design permits ready accessibility and easy maintenance of all equipment

Figure 8. Essential components of an individual section drive as applied to a machine equipped with the multiple generator type of sectional electric drive

Section speed regulation is obtained by control of its generator shunt field excitation. The draw adjusting rheostat alters the magnitude of the reference signal to which the speed signal from section tachometer is matched

Multiple Generator System

In this system, Figure 3, individual generators are used to furnish power to each of the section driving motors. The complete section control includes the speed regulator, a speed indicating tachometer, magnetic control and the operator's control station. A master cubicle (Figure 6) contains an electronic voltage regulator for the constant voltage exciter, control for all motor and a-c tachometer fields, statically regulated master reference source and motor operated rheostat for controlling speed of the over-all machine. The master reference, section a-c tachometer, section control stations, and master control station are the same as those used with the single generator system.

The multiple generator system offers distinct advantages over the single generator system. The applied armature voltage to each section drive motor is correct for all productive speeds of the machine. Because of this fact standard motor frame sizes may be used regardless of the productive speed range. More important from the standpoint of performance, speed regulation of the individual drive by control of applied armature voltage rather than shunt field excitation of the section motors affords greater stability over much wider operating speed ranges. Speed ranges of 10-to-1 are handled easily. Moreover, since shunt field excitation is constant, regulation is obtained at no sacrifice in motor torque per ampere. Thus, better response is obtained with a narrower range regulator than is required with the single generator system. Since each section control is self-contained in its own totally-enclosed cubicle, no interconnecting heavy bus system or elaborate interlocking of sequencing controls common to all sections are required.

With the multiple-generator system, acceleration under current limit control and deceleration with controlled regenerative braking as well as inching both forward and reverse and wash-up speed are all obtained with the electronic control. The only magnetic devices necessary are the overload relay and the main line contactor which serves as a circuit interrupting device for protection of equipment and personnel.

The speed regulating equipment included in the complete section control cubicle shown in Figure 7 is essentially the same as one of the section regulating units contained in the regulator cubicle shown in Figure 4 used with the single generator system. Operation of the electronic regulator used with the multiple generator system is similar to the operation described under the single generator system. However, in this case, the controlled rectifier furnishes excitation to the section generator to produce a motor armature voltage as required for normal speed as shown in Figure 8.

Electronic Circuits

The error detector element of the electronic regulator is shown in block form in Figure 5 and Figure 8. A simplified schematic of this error detector is shown in Figure 9. This element of the regulator consists of two input transformers, a twin triode tube, capacitors, resistors, and other components required for the d-c power supply.

Figure 9. Simplified circuit of error detector

The isolating transformers 3T and 4T prevent leakage currents and effects from spurious magnetic fields from interfering with regulator performance. The error signal appearing across the cathode resistors is filtered and a portion then amplified

Figure 10. Simplified schematic diagram of voltage amplifier showing sensitivity control as well as antihunt and current-limit feed-back circuits

Figure 11. Circuit elements of the 3-phase grid-controlled thyratron rectifier which supplies excitation to the section motor or generator shunt field in accordance with the input signal from the voltage amplifier

The master speed control rheostat, together with the draw adjusting potentiometer are set to provide a 60-cycle reference voltage corresponding to the desired speed for the section. This voltage is applied to the grid of one of the sections of the twin triode tube through an isolating transformer. The a-c tachometer voltage is connected through an isolating transformer to the other grid of the twin triode tube. Pulsating d-c voltages appearing across the two cathode resistors are proportional to the a-c signal voltages. When the tachometer and reference voltages are equal, the current through the two sections of the tube are equal and the voltage output of the error detector is zero. The pulsating d-c voltages are filtered, then compared and the difference voltage again filtered to provide a d-c error voltage which is proportional to the deviation from the desired speed of the section motor. The error signal is modified in value depending upon its rate of change. This provides a field forcing action for rapid changes in section motor speed.

Use of the isolating transformers precludes the possibility of erratic performance which might result from leakage currents or spurious magnetic fields in or around the long conduit runs from the section drive location and the regulator cubicle. As a further precaution, internal impedances are kept as low as possible.

The voltage amplifier shown in Figure 10 is two stage direct coupling consisting of two twin triode tubes, resistors, capacitors, and other components as required for the d-c power supply.

The d-c error signal from the error detector is applied to a potentiometer from which a portion of the error voltage is used in order to control the sensitivity of the system. The selected portion of the error signal is then applied to one section of the twin triode tube which causes the output of one section to increase or decrease depending on the polarity of the input voltage. The other section of this twin triode tube is connected to the antihunt or negative feed back circuit. The antihunt voltage is proportional to the rate of change of motor field current or generator voltage (depending on the system used) resulting from the regulating action, and is in a direction to oppose any change in these quantities. The output of the two elements of this twin triode tube are approximately balanced when no error signal exists.

The second stage also includes a twin triode tube which further amplifies the output of the corresponding section of the first stage. Current limit control can be introduced in this stage. This may be accomplished by measuring the magnitude and polarity of armature current, amplifying this signal and feeding it into the input of the second stage. If the motor armature current exceeds a preset value, the current limit signal will predominant over the error and antihunt signals from the first stage thus limiting the regulator action.

The amplified output of each triode section of the second stage is connected in a bridge arrangement and the positive or negative difference is applied to the controlled rectifier.

The controlled rectifier shown in Figure 11 consists of three thyratrons, phase shift circuit, and transformers. The phase shift circuit is designed to shift the voltage on the grids of the thyratrons 120 degrees lagging with respect to their anode voltages.

The d-c voltage from the amplifier is applied to the grids in series with the fixed phase shifted voltage. Variation of the d-c component of this grid voltage controls the output of the thyratrons over their full range from minimum to maximum. The 3-phase rectifier output is then applied to the field of the section motor or section generator depending on which system is used. The speed of the section motor is thus controlled by the output.

The decision to use a controlled rectifier for motor or generator field excitation rather than a rotating machine was based on the desire to eliminate all possible commutating machines with their attendant maintenance and inconsistencies from the regulating circuit. More important, perhaps, was the aim for the quickest possible regulator response.

Conclusions

The all-electronic regulating system has been applied to a number of machines producing widely different types of paper including tissue, book, and kraft. Operating experience indicates that the overall system design is sound. The use of an a-c speed cue permits isolation of circuits which are often troublesome. The electronic exciter for motor or generator excitation eliminates the necessity of a multiplicity of rotating units in the regulating system.

The sag-back problem is no longer a menace to successful operation of high-speed kraft machines. Quick responding electronic regulators have measured up to the task.

As with all precision equipment a carefully planned maintenance program is essential to the continued high-level performance of which these systems are capable. The most important part of such a program is periodic testing of all high vacuum tubes. Specific limits should be set on tube characteristics and all tubes falling below these limits should be discarded. New tubes should be tested before they are installed. Records of tube characteristics as well as operating life and reason for replacement should be kept.

No Discussion

System Operation Improved With Carrier Telemetering and Load Control

A. W. WALTON
MEMBER AIEE

H. W. LENSNER
ASSOCIATE AIEE

THE POWER systems in the Southwest were banded together during the war to provide adequate capacity for supplying energy to large war industries located there. To insure delivery of power and to assist the dispatchers in maintaining schedules and co-ordinating distribution of generation throughout the area, certain sections were equipped with extensive carrier communication, telemetering, and automatic load control facilities.

In the Oklahoma district, operating companies were set up as one operating area. Similarly, areas in adjacent states were delineated as determined by engineering considerations.

Since the war, the need for co-ordination between areas has been supplemented by the need to properly co-ordinate and control inter-system interconnections within the areas originally set up. In place of co-operating to supply a common load, it has become increasingly necessary for each system to carry its own loads. Effective scheduling of hydro and thermal generation could only be obtained by giving the system load dispatcher the proper load information at strategic points on the system.

Transmission System

The Oklahoma Gas and Electric Company transmission system extends through the central part of Oklahoma from the Texas border to the Kansas border, also east into the state of Arkansas. Figure 1 shows a block diagram of the power systems of Oklahoma and interconnections. There are eight interconnections; one with the Kansas Gas and Electric Company, another with the Southwestern Power Administration, two with Grand River Dam Authority, and four interconnections with the Public Service Company of Oklahoma, most of which are closed for normal operation.

Problem

In order to provide smooth and efficient operation of this power system, the following features for a telemetering and load control system were required:

1. Load information on generating stations and tie lines.
2. Provision for totalizing net load on all interconnections.
3. Load control based on tie line bias or system frequency.
4. Communication facilities between load dispatcher and generating stations.
5. Provision for adding telemetered quantities to allow for expansion of power system.

The Telemeter System

The eight interconnections, an intrasystem tie line and four of the largest generating plants are telemetered into the load dispatcher's office located in Oklahoma City. Power line carrier channels are used extensively because of the distances of transmission.

In order to obtain a co-ordinated system of control, the tie line recorders in the load dispatchers office are arranged so that the net or algebraic sum of all interconnections is continuously recorded, and that the net or any combination of tie lines can be controlled. The latter requires a separate tie line bias recorder.

Figure 2 shows a simplified diagram of the recorders and control. The re-transmitted output of the tie line recorders is fed into the net interchange recorder. Another set of re-transmitters on the tie line recorders, the output of which can be switched, is fed into the tie line bias recording controller. The system frequency recorder contains the controls for bias settings.

The generating plant recorders A, B, C, and D are also shown. The manually-operated potentiometer E simulates the output of small nontelemetered generating plants. The output of the net interchange recorder and the generating plant load recorders is fed into the net system load recorder.

The master load frequency controller is

A. W. WALTON is an electrical engineer with the Oklahoma Gas and Electric Company, Oklahoma City, Okla., and H. W. LENSNER is a design engineer with the Westinghouse Electric Corporation, Newark, N. J.

Figure 2. Block diagram of telemeter recorders and control plan

responsive to the tie line bias controller and the system frequency meter and originates the load control impulses. The Horseshoe Lake generating plant was selected as the regulating station to control the tie lines.

Figure 3 shows the arrangement of tie line, generation and system load recorder panels and control equipment. The load dispatcher's recording and load controlling equipment as finally adopted incorporates the following general features:

1. Operates under different types of control, including frequency control when the system is isolated, flat tie line and tie line bias control.
2. Is able to control the net interchange on any tie line or combination of tie lines.
3. Has a wide range of adjustments in the load control equipment.
4. Has a wide range in bias settings.
5. Provides a continuous record of the net interchange.
6. Provides a record of the net system load.

Terminal Telemeter Facilities

The interconnected tie line terminals are equipped with high rate impulse telemetering transmitters for controlling the tone modulated carrier transmitters. In the generating plants the output of high-speed 3-phase thermal devices connected in each generator metering circuit is totalized in a total station load recorder which originates the impulses and controls the carrier transmitter.

The station load recorder has the following features:

1. Provides a graphic record of the total station output.
2. Integrates the total station output.
3. Originates the telemeter impulses to control a carrier transmitter.
4. Controls a boiler room total station load indicator or indicators.
5. Controls a meter which records the station hourly demand.

Carrier Considerations

From a consideration of the extent of the system over which the telemetered quantities had to be transmitted, power line carrier was decided upon for the channels to transmit information to the load dispatcher at Oklahoma City. Figure 4 shows the distances between stations on the power system. The total distance from the most remote substation to the load dispatcher is about 270 miles and includes seven line sections requiring one radio-frequency by-pass at Reno Street. Also, at each station there are one or more other line sections connected to the bus which will divert some of the carrier energy away from the desired channel. The carrier energy divides roughly in proportion to the number of lines radiating from a station bus, so for example, if there are four lines connected to a bus, only one-fourth of the carrier energy will go down the line toward the intended receiving terminal. This applies only to electrically long, nonresonant lines. For short lines an odd-quarter wavelength long, the carrier losses may be very high.

Numerous transformer banks are located along the lines and at the various stations, and while in general a power transformer does not absorb appreciable carrier energy, there are so many that they cannot be neglected. For example, between Fort Smith and Riverbank (including the line and two station busses) there are 12 transformer banks. Several of the line sections have short taps on them and these in particular restrict the choice of frequency.

A survey of the use of the 50–150 kc carrier band in the area disclosed the fact that this range of frequencies was being utilized very nearly to capacity and left insufficient channels for the telemetering system contemplated. Actual monitoring at widely separated points confirmed this fact. In view of this condition, it was necessary to go outside the 50-150 kc band for sufficient channels. Frequencies as low as 30 kc were being used, and the majority of the telemetering signals are between 150 and 250 kc, with provisions for going as high as 300 kc if necessary.

Figure 3. Telemeter and load control panels at load dispatcher's office in Oklahoma City

Since attenuation increases with frequency, it was apparent that satisfactory operation of single carrier circuits over as much as 270 miles of the system would be unsatisfactory with standard carrier equipment because there would be insufficient margin between the calculated circuit attenuation and the maximum capability of the equipment. High power transmitters were considered, but this would be undesirable because of excessive radiation at the higher carrier frequencies, which might result in interference with other services. In view of these facts, it was decided not to transmit carrier signals from the most remote stations all the way to the load dispatchers at Oklahoma City without repeat stations along the way where the signal levels could be boosted. The total distance of 270 miles from the most remote point with six intermediate stations and numerous additional lines diverting carrier energy would give a poor signal-to-noise ratio at the receiving end if only a single carrier channel were used for the entire distance.

This problem was met by using standard carrier transmitters and two repeat stations to maintain a favorable signal-to-noise ratio. In addition, a line trap was used at Riverbank to isolate lines and busses which otherwise would have absorbed a large percentage of the carrier energy.

In order to utilize each carrier channel as much as possible, tone modulation of the carrier signal was employed so that several telemetered quantities could be transmitted over a single carrier channel.[1] In this way the number of quantities that could be transmitted in a given channel space was greatly increased. Even in cases where only a single quantity was transmitted from a station, audio tones were used for uniformity and to allow for future expansion.

With a carrier system employing tone modulation, there is also the possibility of doubling the available carrier channels by conversion to single sideband modulation.[3,4] This provides for future expansion of the telemetering system without rendering the existing carrier equipment obsolete. The same carrier components are used, and it is necessary only to add the units which will convert a conventional double sideband amplitude-modulated carrier system to single sideband operation. Whereas a conventional amplitude modulated carrier channel employing ten tones with frequencies up to 2,900 cycles requires a channel approximately 6 kc wide, with single sideband equipment the same information can be transmitted over a channel only 3 kc wide, and with an improved signal-to-noise ratio. This is brought about because in the single sideband system all the carrier energy is in the sidebands, and the base carrier frequency is supplied at the receiving terminal from a stable oscillator.

Figure 5. Block diagram of carrier and tone channels for communication, telemetering, and load control

The System Adopted

Figure 5 shows a block diagram of the essential elements of the carrier telemetering system. From Howe and Fort Smith, 150- and 209-cycle tone modulated signals of two different carrier frequencies (*f1* and *f2*) are transmitted to Riverbank where they are received on two carrier receivers whose outputs are connected in parallel to energize two tone receivers. The output relays of these two tone receivers in turn control two tone transmitters of the same frequencies (150 and 209 cycles) which modulate another carrier signal (*f3*) transmitted to Horseshoe Lake. In addition, 290-cycle and 403-cycle tones keyed by the quantities to be telemetered from Riverbank are impressed on the same carrier frequency, to Horseshoe Lake, which now contains the telemetering signals from Howe, Fort Smith, and Riverbank.

This method of repeating has the advantage of eliminating all noise that may be present in the output of the receiver whose signal is being repeated. The tone receiver relay keys another tone transmitter, and essentially the signal starts all over again on a different carrier frequency.

Provision has been made in this part of the system for a communication channel between Riverbank, Fort Smith, and Howe, separate from the existing 50-kc carrier communication system. This was provided to handle the load dispatching and reporting in of miscellaneous infor-

Figure 4. Part of the Oklahoma Gas and Electric system considered for carrier telemetering and load control

Figure 6. Low-pass carrier filter to suppress harmonics, and attenuation curve of filter

mation to Riverbank from Howe and Fort Smith without tying up the main communication channel.

From most of the other stations on the system, a single quantity is transmitted by tone modulation. Although unmodulated carrier on-off keying could have been employed from each of these stations, provision was made for future expansion where it would be desired to transmit more than one quantity from each station. These stations include Sapulpa, Drumright, and Seminole. Two audio tones are transmitted from Beerbower station. All the signals from the outlying stations are received at Horseshoe Lake on a total of five receivers. The audio frequency outputs of these receivers are connected in parallel in two groups as shown in Figure 5, together with one tone transmitter for the local generation and one tone for repeating Denison Dam interconnection. Each of the two groups is retransmitted on a different carrier frequency (*f8* and *f10*) from Horseshoe Lake to the load dispatcher at Oklahoma City where the final tone receivers and recorders are located.

The question might be raised as to why another repeat station was used with only 25 miles of line remaining to the ultimate receiving point. It will be noticed that there is a high-voltage regulating station at Reno Street, and it is necessary to use a carrier by-pass around the regulating transformer and circuit breakers. The cost and complexity of carrier by-pass equipment for 11 carrier channels would have been prohibitive. Instead, only a double frequency by-pass is needed, and its tuning is broad enough to pass the carrier frequencies for the telemetering signals, and another frequency (*f9*) transmitted from Oklahoma City back to Horseshoe Lake for load control.

After the received telemetered quantities are routed to the respective recorders, they are then totalized for the desired quantity for controlling generation by means of "raise" and "lower" impulses. These impulses control two audio tones which are transmitted over another carrier channel back to the Horseshoe Lake station. The load control impulses are received at Horseshoe Lake through two tone receivers and then routed to the governor of the turbo generator selected for regulation.

Carrier Equipment

Standard commercial power line carrier equipment has been used on this installation. The design of carrier units for the 150-300 kc band presented no particular problems but amounted primarily to a change of the constants of the tuned circuits of the component units. Coupling capacitors, line tuners, and line traps behaved essentially the same as at lower frequencies with negligible increase in losses.

One unit requiring particular attention was the carrier transmitter which must operate with very low harmonic distortion in its output. This is particularly important in the 150–300 kc range since low order harmonics fall in the standard broadcast band. To aid in suppressing harmonic output, a low-pass filter was connected between the output of the car-

Figure 7. Front view of load recorders and control equipment in load dispatcher's office, Oklahoma City

Figure 8. Front view of carrier equipment at Riverbank Station

This assembly includes audio and carrier frequency units for a relay repeat of two telemetered quantities, and for communication with Howe and Fort Smith

rier transmitter and the coaxial cable. This filter introduces negligible loss in the carrier frequency range up to 300 kc, but a high attenuation in the broadcast band, as shown in Figure 6. The filter also has an attenuation peak in the vicinity of 450 kc to prevent interference arising from carrier harmonics getting directly into the intermediate frequency section of broadcast receivers. With the equipment properly installed and adjusted, no radio interference was encountered.

The equipments operate from a-c power supplies to reduce the station battery load. The transmitters have an unmodulated carrier output of $7^1/_2$ watts and are capable of nearly 100 per cent modulation. Two types of receivers are used: superheterodynes for most of the channels, and tuned radio-frequency receivers for short channels where the carrier attenuation is low. Both types of receivers are provided with automatic volume control to restrict the variation in audio output for variations in the level of the carrier signal.

Conclusions

This carrier telemetering and load control system has been in operation for over a year and has effected more efficient and economical operation of the power system because of the load information supplied to the load dispatcher, and the automatic load control feature. A continuous record of the net interchange between systems has been kept, as well as the load on each large plant and the total load of the system. Personnel have been trained for preventive maintenance to insure continuity of operation of the equipment.

Provision has been made to allow for future growth when it will be necessary to add more telemetered quantities and load control channels without making the existing equipment obsolete. The transition from manual to automatic load control on this power system has begun, and the experience gained today will be translated into further improvements in the future.

Discussion

R. W. Beckwith (General Electric Company, Syracuse, N. Y.): As we gain experience with extensive telemetering applications such as this we now see that another type of carrier equipment described in another paper[1] could be applied resulting in a simplified system using much less of the frequency spectrum. Crystal-controlled frequency-shift channels for each telemeter reading could be closely spaced in frequency and the group treated as one carrier channel. A thorough study might show that the Fort Smith and Howe readings would have to be repeated at Riverbank. These two readings could be transmitted to Riverbank on closely adjacent frequencies forming a second carrier channel. With this arrangement no single tube failure could interrupt more than one channel. Independence of automatic volume control on each channel would eliminate any possibility of severe changes in line attenuation disrupting a reading.

C. W. Boadway (The Hydro Electric Power Commission of Ontario, Toronto, Canada): The paper indicated that a complicated problem of power line carrier for telemetering and load control was quite evident in the system as operated by the Oklahoma Gas and Electric Company. It would appear from the data collected for the paper that the transmission line under discussion was to some extent a distribution type in that numerous taps were involved which did not allow the communication or carrier engineer a straightforward carrier transmission problem such as might be found in a direct terminal to terminal installation. The lack of wave traps in a system of this kind adds to unfavorable possibilities of power carrier transmission under adverse weather conditions.

Under Carrier Considerations, the attenuation for bus coupling was described. It leaves the impression that bus coupling was actually used quite frequently; however, in practice this is not the case. In order to obtain higher efficiency from transmitter-receivers, phase-to-phase and phase-to-ground coupling are used much more extensively.

On the matter of tap lines it was stated that with electrically long tap lines the radio-frequency energy divided equally between the tap and the desired line, and that on electrically short lines considerably high frequency losses may be incurred. However it was not mentioned that a short tap line may be changed to act as an electrically long line by terminating the line by its characteristic impedance, or that its effects may be cancelled completely by using a line trap in the short tap. The particular problem of the length of untrapped tap lines and the choice of the frequency of the carrier may have been included in this discussion. The frequency of the carrier may be so chosen that no excessive losses result by reflection due to the length of the line being an odd-quarter wave length.

On the discussion of the 270-mile telemeter channel, it was emphasized that due to the length of the line the attenuation was so great that it was necessary to use carrier transmitter receivers to amplify the signals. It may be added that since telemetering quantities at an intermediate point would be valuable to system operators, the quantity may be recorded at the intermediate point and then retransmitted. This possibly is being considered for future operations.

D. M. MacGregor (Ebasco Services Incorporated, New York, N. Y.): Walton and Lensner have given us a very clear and concise description of a rather complete installation of tie-line telemetering and load control equipment. As in so many other cases, the initial, limited installation of this type of equipment served to illustrate both the usefulness of the equipment as an operating aid and the need for a more complete installation. Several of the essential features of a well-designed installation, such as a careful choice of quantities to be recorded, are covered very well in the paper. Two or three other points seem to deserve further discussion.

Higher speed telemetering and control equipment has long been considered desirable by many operators. The equipment described in this paper has relatively long over-all response time as compared to some of the newer systems which are or will soon be available. It would be of interest to know if operating experience with the Oklahoma system has indicated the desirability of using the higher speed equipment, especially with respect to control of low-capacity tie lines.

Interconnection telemetering is usually of interest to both of the interconnecting groups and, for that reason, the telemetering system and the carrier facilities should be suitable for use by both companies, if possible. The paper does not indicate whether or not this feature was considered when designing the Oklahoma Gas and Electric Company installation.

The power-line carrier-frequency spectrum is quite limited and, in many cases, crowding of this spectrum is proving to be a serious limitation on further expansion of carrier telemetering facilities. It would be interesting to know the reasoning which dictated the choice of audiotone carrier telemetering for all channels as compared to the frequency-shift system, since the latter system is generally regarded as being very economical in use of channel space for interconnection telemetering. Audio-tone equipment appears to be best suited to those installations where at least three quantities are telemetered from a single point. The greater sensitivity of frequency-shift equipment usually makes it unnecessary to repeat signals at intermediate points so that the complete system develops into one or two groups of closely-spaced channels originating

at numerous remote points and all terminating at the central control and recording station. Under these conditions, the use of carrier-spectrum space is a minimum as compared to the apparently greater use involved with the audio-tone system. Actual frequencies used on the Oklahoma Gas and Electric Company system are not indicated in the paper but it appears that channel spacing must be fairly wide and that the system must use a relatively large portion of the frequency spectrum. It would appear that some saving of channel space would have been possible by use of frequency-shift equipment at least on all channels originating west of Riverbank.

A. W. Walton and **H. W. Lensner:** The authors are well pleased to see the interest shown in the subject of carrier telemetering. While power line carrier is well established as a medium for telemetering and other functions, each application uncovers new problems in setting up a reliable channel, determining the type of carrier transmission (keyed, modulated, and so forth) and utilizing the quantities received. This ever-changing picture presents a constant challenge to the engineer of both the manufacturer and the user of the equipment.

The discussers have shown much concern regarding the crowding of the carrier spectrum, attenuation and line traps, and rightfully so. The problem became apparent when it was found that the 50–150 kc carrier spectrum was already well utilized in an adjacent public power area by many existing duplex carrier communication installations which paid the price of channel space for the duplex feature. This greatly restricted our choice of frequencies, and as stated in the paper, we were forced to go into the 150–300 kc spectrum. We refer Beckwith to our paper describing the repeater stations at Riverbank and Horseshoe Lake. Tube failures are negligible. For Boadway's information, the telemetered quantities repeated at Riverbank were also diverted for local use.

MacGregor is quite correct; the initial installation was limited because of inability to obtain adequate equipment during the war. Our program which is now under way includes line traps wherever necessary and the gradual elimination of bus coupling and its attendant high carrier losses resulting from diversion of carrier energy from the desired path.

The points MacGregor raised are of interest. Higher speed telemetering and control equipment would be very desirable, particularly for controlling our low capacity tie lines. A neighboring utility does make use of some of the telemeter channels. As will be noted, the Horseshoe Lake terminal serves as a gathering point for all telemeter quantities and thence is repeated by audio tones over two carrier channels to the Oklahoma City terminal. Economics dictated audio tone equipment for the latter section. Likewise, when the system is expanded to include more telemeter quantities such as reactive kilovolt-amperes, it will be economically feasible to do so by merely adding more tone units to the existing carrier transmitters and receivers. The carrier system has given a very good account of itself and the telemetering and load control have become an indispensable tool in system and interconnected operation.

Characteristics of New Carrier-Current Equipment for Telemetering and Load Control

R. W. BECKWITH
ASSOCIATE AIEE

THE RAPIDLY expanding use of telemetering by power companies is made possible largely by carrier-current channels. Anticipating the requirements of present day telemetering needs a narrow-band frequency-shift type of equipment was developed. This equipment has received wide acceptance and the many channels which have been in successful operation for some time have confirmed the value of the design features.

A review of the forms of telemetering now in use with carrier-current channels shows that in some cases the carrier transmitter must be controlled by a single opening and closing contact and must duplicate this contact performance at the receiving end. In one frequency type of telemetering[1] the carrier transmitter must accept a variable, low-frequency alternating voltage and must reproduce this voltage at the receiver output terminals. In order to make possible the use of the maximum number of carrier-current channels on a given power system, it becomes very important to conserve the carrier-frequency spectrum and utilize the minimum possible power. Since many telemeter channels are required to operate over long distances, the equipment must be capable of operation through high attenuation with good independence from noise, interfering signals, and wide changes in attenuation. This paper describes a new type of carrier-current equipment which fulfills these requirements.

The substantiated theories of frequency modulation[2] have been applied to the signals from 0 to 30 cycles per second as required for telemetering. This shows that the use of a very narrow-band frequency-shift system[3] will provide the greatest useful range per unit of transmitted power.

Of equal importance to range, these principles indicate a more economical use of the carrier frequency spectrum and excellent independence of received telemeter signal from variation in received carrier voltage.

Quartz crystal circuits are used to generate the frequency-shift signal and to detect the small (0.06 per cent) shift in transmitted frequency. The receiver uses a crystal filter and crystal discriminator. One type of transmitter uses two crystals and a means for switching output. Another type uses a single crystal and reactance tube circuit for shifting frequency.

An important feature of the equipment is the independent operation of each channel, while at the same time many channels can operate through common coupling and tuning equipment. As many as 25 channels can be accommodated in a 12 per cent wide frequency band. A valuable flexibility results from the fact that it is not necessary for all transmitters of a group to be located at one point, making it possible to transmit a number of telemeter readings from several outlying stations to a central control point, all in the same band of frequencies. It is possible to transmit two groups of telemeter frequencies in opposite directions with 5 per cent separation between groups. Unidirectional channels in each group are spaced 0.5 per cent apart.

Paper 48-297, recommended by the AIEE carrier current committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted August 2, 1948; made available for printing September 7, 1948.

R. W. Beckwith is with the carrier-current section, transmitter division, General Electric Company, Syracuse, N. Y.

This material is part of a thesis presented to the Faculty of the Graduate School of Syracuse University in partial fulfillment of the requirements for the degree of Master of Electrical Engineering.

General Objectives

Carrier-current equipment has been developed to meet the following objectives, keeping in mind the requirements of the telemetering instruments in common use.

1. The equipment should require the minimum frequency space consistent with necessary bandwidth required by the nature of the signal.
2. It should make possible the use of low-power transmitters and maximum operating range by obtaining the best possible freedom from effects of power-line noise.
3. The greatest reliability should be obtained by making the operation of the equipment essentially independent of line attentuation variations.
4. It should provide maximum versatility and reliability by making each channel independent as far as electronic circuits and eliminating any requirement that all transmitters be at one spot and all receivers at another. For economic reasons, it should make possible maximum joint use of coupling and tuning equipment.

Fulfillment of the first two objectives directly contributes to reducing frequency congestion. Fulfillment of the fourth objective results in greatly simplifying a system requiring a number of telemeter readings to be brought from several outlying points to a central dispatcher's headquarters.

These readings can be transmitted on closely adjacent frequencies, and the entire group treated as one "wide band" carrier channel, rather than separate "wide band" channels from each outlying station. Often a reading can be transmitted on one frequency that otherwise, because of the large attenuation, would have required two tandem channels on separate frequencies.

Figure 1 (left). Block diagrams of receiver and two types of transmitter

Figure 2. Crystal discriminator (A) circuit diagram (B) crystal characteristic, (C) discriminator circuit characteristic

Frequency-Shift Operation Selected

Frequency-shift type of transmission was chosen, since at the receiving point two steps can be taken (in addition to frequency selection) to provide greatest freedom from the effects of line noise. The first, an amplitude limiter,[2] well understood from its use in frequency-modulation receivers, also provides independence from variation in line attenuation up to the full operating range of the equipment. The second, a discriminator,[3] also well understood from its use in frequency-modulation receivers, provides excellent cancellation of noise. This latter circuit could be thought of as analogous to a polarized relay which will not respond to rapidly fluctuating interfering currents but will move one way for a steady current in one direction, and move the other way for a steady current in the other direction.

Crystal Operation

The transmission of such a recurring function as a telemeter signal can be analyzed on much the same basis as voice transmission. For voice, a band of frequencies from about 300 to 3,000 cycles per second must be transmitted. The usual telemetering signal, whether impulse or frequency-type, is made up of very low-frequency components with a maximum value of about 30 cycles per second.

One type of impulse duration telemetering uses a total cycle of 2.4 seconds. A Fourier analysis of such a signal will show that the lowest frequency to be transmitted is considerably less than one cycle per second. The shortest impulse to be transmitted is 0.1 second, equivalent to 5 cycles per second. In order to approximate a square impulse some third harmonic or 15 cycles per second should be transmitted. We may therefore conclude that a band of frequencies up to 15 cycles per second must be transmitted. In another frequency-type telemetering,[1] a 6-to-27 cycle-per-second band is required.

It has been demonstrated by those working with frequency-modulated voice transmission,[4] that the greatest range is obtained by a deviation ratio of one. (Deviation ratio is the ratio of frequency swing each side of the carrier frequency, to the highest modulating frequency.) Since the same principles must apply for the lower frequencies below 30 cycles per second, an optimum range for telemetering would require a frequency shift of about 60 cycles.

The very narrow bandwidth desired strongly suggested the use of quartz crystals as this was the only practical circuit element which combined the necessary stability and high "Q" requirements. As a further contribution to the elimination of frequency congestion between 50 and 150 kc, the equipment has been designed to cover a range from 30 to 200 kc. The equipment is designed for two frequency ranges, one 30 to 90 kc and the second 90 to 200 kc. "Flexure mode" crystals, requiring slightly different circuits, are used below 90 kc, resulting in excellent stability while at the same time permitting a large reduction in size over more conventional cuts.

The Receiver

Figure 1(A) is a block diagram of the receiver, a tuned radio-frequency design chosen for simplicity and stability. This receiver uses a crystal filter ahead of the first amplifier tube. This filter was especially designed to provide the band-pass characteristic necessary to pass the two transmitted frequencies (high-shift and low-shift) and at the same time give maximum selectivity above and below the operating frequencies. Since this crystal filter is placed before the first tube, the greatest part of the frequency selection is performed before any undesirable mixing of frequencies can take place due to nonlinearity in the first tube. The crystal filter is followed by two double-tuned radio-frequency circuits with the associated amplifier tubes, an amplitude limiter stage, a crystal discriminator stage, and either a relay tube or a low-frequency amplifier.

The circuit which is the heart of the proposed system is the receiver discriminator. It can be seen from Figure 2(A) that the crystal discriminator circuit consists of a bridge which is symmetrical with the exception of crystal *Y1* and capacitor *C1*. From the reactance curves of the crystal and capacitor, shown in

Figure 3. Receiver operating characteristic

Figure 4. Assembly of eleven parallel-connected carrier-telemeter receivers

Figure 5. Block diagram of radial type of application

Figure 2(B), it can be seen that these also balance above and below the resonant region of the crystal. At point P, the crystal has a low resistive impedance and so the current $i2$ exceeds current $i1$, and a negative output voltage results. At point Q, the crystal has a high resistive impedance and the current $i1$ exceeds $i2$ and a positive output voltage results. The resultant characteristic curve is shown in Figure 2(C).

The unique features of this circuit are the very narrow frequency spectrum used (about 0.06 per cent between positive and negative peaks) and the fact that the frequency occurrence of the peaks is almost entirely controlled by the crystal itself. Since for greatest stability it is desirable to shift the transmitted frequency from the positive to the negative peak, the crystal discriminator fixes the frequency shift to about 0.06 per cent. Although this shift is not exactly the same at all carrier frequencies, crystals may be duplicated at any one frequency allowing replacement of crystals and allowing the operation of more than one receiver from one transmitter.

Figure 3 shows three characteristic curves taken on an actual receiver. Figure 3(B) is a selectivity curve from receiver input to the limiter grid and includes the crystal filter selectivity plus the selectivity of the tuned amplifier. This curve shows the relative input necessary to maintain constant limiter grid current as a function of frequency and was taken with automatic volume control off. The curve passes through zero decibels at the high-shift and low-shift transmitted frequencies. Figure 3(A) was taken by introducing an interfering signal into an operating channel. The ratio of interfering signal to desired signal voltage at the receiver input terminals is plotted at the threshold of interference to the receiver. In the region above the curve, therefore, operation of the channel is impossible, but below the curves operation is unaffected by the interference. The improvement of this curve over Figure 3(B) is due to the additional selectivity of the crystal discriminator circuit. Figure 3(C) shows the crystal discriminator output voltage as a function of frequency, plotted to the same frequency scale as Figure 3(A) and Figure 3(B).

Table I

The Transmitter

Figure 2(B) is a block diagram of one type of transmitter which utilizes two crystals ground to match the positive and negative peak of the associated receiver discriminator characteristic. These crystals operate continuously in separate oscillator circuits and each drives an associated buffer stage. Keying of the buffer stages therefore causes a shift in output frequency, and produces a positive or negative output voltage from the associated receiver discriminator. In order to accommodate keying either by a voltage or by a keying contact, another transmitter shown in block diagram in Figure 1(C) is used. This transmitter makes use of a single quartz-crystal oscillator which includes a reactance-tube circuit in such a way that this circuit will cause the necessary small shift in output frequency. By applying the keying voltage to the reactance-tube grid circuit the carrier frequency can be varied in accordance with this voltage.

Application

Groups of these transmitters may be spaced at 0.5 per cent intervals of fre-

Figure 6. (left) Block diagram of 2 - directional type of application

Figure 7. (right) Block diagram of combination of a 2-frequency duplex telephone channel and a telemeter channel in each direction

quency. A space of either 0.5 per cent or 1.0 per cent may be left between adjacent channels of two different groups of transmitters depending upon the application. Two-direction channels are possible by leaving a 5.0 per cent spacing between groups of channels transmitting in the two directions.

This equipment is extremely versatile in its application as shown by the following typical examples.

Multistation Radial Application

It is often desirable to transmit telemeter readings from a number of generating points, inter-system tie points, and so forth, to a central dispatching station of a power company. Figure 4 shows such an equipment now in operation. One or more readings may be received from each such point and utilized individually, or they may be totalized in various combinations. In addition, a particular reading or some form of automatic load control signal may be transmitted from the central dispatching station to one or more generating points. Crystal-type carrier telemetering equipment lends itself very well to such an arrangement in that as many as 25 such channels may be grouped in a 12 per cent wide frequency band and handled as one carrier frequency using single-frequency transmitter and receiver tuning equipment, by-passes, and line traps.

All receivers are merely connected in parallel with the line tuning adjusted for a mean frequency, and with each receiver input circuit adjusted to the frequency of its associated transmitter. The major part of the frequency separation is not achieved by the receiver input circuits, however, but by the crystal filter circuits. Figure 5 shows a typical assembly of eleven receivers all operating in parallel on the same channel.

All transmitters at each transmitting point are connected in parallel and tuned to the line by single-frequency tuning units. When connected in parallel, each output amplifier tube has impressed on its plate the voltages of each of the other transmitters. It is reasonable to require that the total plate voltage swing, with two or more transmitters in parallel, must not exceed that for one transmitter. This means that the total peak output voltage must remain constant and the voltage output of each transmitter must be reduced as the reciprocal of (n), the number of parallel transmitters. This results in a reduction of the operating range of the equipment in accordance with Table I.

The coupling between plates of the various amplifier tubes is less than unity and the realized losses are smaller than those indicated, therefore, Table I is very conservative. Of course, no reduction need be made for adjacent channels located at some other transmitting point because of the separation between transmitters afforded by line attenuation. Each transmitter group is therefore considered only on the basis of the number actually connected in parallel at one station.

Although the laboratory range of the equipment is in excess of 100 decibels a conservative operation range of 85 decibels (with a 2-watt transmitter) has been assigned as an application guide under average line noise conditions.

Two-Direction Arrangement

Two-directional channels can, of course, be arranged by conventional 2-frequency tuning of the coupling capacitors at each end of the line. With the high selectivity afforded by the crystal equipment an arrangement such as Figure 6 can be made which is economical both in cost and frequency spacing. A transmitter and receiver may be connected in parallel at each end and tuned by common single-frequency line-tuning equipment. In this case the transmitter is decoupled by means of a small resistance. A frequency spacing of 5.0 per cent is used between frequencies and the equipment when so used is rated at 70 decibels with a 2-watt crystal-controlled frequency-shift transmitter. Additional channels may be added in either or both directions at a spacing of 0.5 per cent above the higher or below the lower of the first two frequencies. A further reduction in decibel rating is made according to Table I on the basis of the transmitters actually tied in parallel at one or the other end of the line. (If the number of channels in each direction is not the same, the decibel rating might differ for opposite directions.) In a 12 per cent frequency bandwidth as many as eight channels can be transmitted in each direction with single-frequency tuning. In fact similar schemes involving more than two stations can be worked out but usually require special consideration.

Combination with a 2-Frequency Telephone Channel

As shown in Figure 7, it is possible to replace the carrier-frequency oscillator of an amplitude-modulated transmitter used in a 2-frequency telephone channel by the output of a frequency-shift telemeter transmitter and thereby provide simultaneous telemetering in either or both directions. By using the reactance-tube type of telemeter transmitter (Figure 1(C)), the shift in frequency is so smooth that no interference is caused in the voice receiver, which responds only to amplitude changes. The telemeter receiver and voice receiver are placed in parallel. Because the telemeter receiver has such sharp selectivity, voice modulation does not affect the telemeter receiver. The telemeter and telephone functions can go on at the same time, entirely independent of each other.

It is also possible to add a low-pass filter in the carrier-current voice receiver output (cutting off at about 3,000 cycles per second) and add a second telemeter channel above and a third below the telephone channel starting 4,000 cycles from the center telephone channel frequency.

In such a combination as described, it is suggested that the first telemeter channel always be used to replace the voice transmitter oscillator because this provides crystal control for the voice frequency and prevents change of this frequency from any cause including "knob twisting" by unauthorized personnel.

Discussion

C. W. Boadway (The Hydro Electric Power Commission of Ontario, Toronto, Canada): The paper definitely indicated an improvement in general frequency requirements as approximately 25 channels can be operated in a 12 per cent wide frequency band thus conserving important carrier frequency allocations.

The paper indicated improved carrier transmission properties as follows:

1. Improved signal to noise ratio (good selectivity).
2. Independent of line changes (limiter and ratio detector).
3. Frequency shift operation (0.06 per cent shift).
4. Independent operation of each telemeter channel.
5. Operates through a common coupling or tuning unit.
6. Spacing of 0.5 per cent for unidirectional channels.
7. Spacing of 5 per cent for bidirectional channels (duplex).
8. Operates well over 85 decibels with 2-watt transmitter.

9. Handles square waves. Pulse duration and so forth up to 10 cycles per second passing three harmonics, that is the bandwidth 30 cycles per second (±30 cycles per second deviation).

10. More than one receiver can operate on one frequency (matched crystals).

11. The receiver stability is essentially independent of all variations except the crystal drift which is negligible.

The paper in general indicated that the multistation radial application up to 25 remote transmitters can transmit intelligence to a central point without exceeding a bandwidth of 12 per cent. It also indicated that at the central station, only one coupling and tuning unit is required and one set of coupling equipment at each group of transmitters. At a 2-directional station, conventional 2-frequency tuning units and coupling capacitors are required. If the line loss is not over 70 decibels and 5 per cent frequency spacing, one 2-watt transmitter with receiver can operate on duplex over a single-frequency line tuning unit. This would also include a maximum of eight channels working duplex over a single-frequency tuning unit.

The application of close coupling channels requires the use of precision type crystal frequency drift, and special attention would of necessity be employed in the tuning of wave traps, particularly in conjunction with the 25 transmitter channels which have a total width of 12 kc.

It is clear that the author and his associates in the General Electric Company have given considerable time and study to the narrow-band frequency-shift type of operation and it should contribute greatly to the users of power line carrier equipments, particularly where numerous channels are involved, thereby reducing carrier frequency requirements.

D. W. Mercer (Ebasco Services Inc., New York, N. Y.): This paper describes an improved type of frequency shift equipment based upon principals of frequency modulation and employing a frequency shift of only 0.06 per cent and capable of operating with only 0.5 per cent separation between channels.

This feature should appeal to those who have the problem of adding telemetering and load control channels on systems where the carrier spectrum is already crowded and where maximum use must be made of the available band widths.

The narrow band widths required and the use of frequencies above and below the 50-to-150 kc carrier range are features which do much to conserve the carrier frequency spectrum. While this appears to be the greatest advantage of this equipment over that previously available, it has many other desirable features including good independence from noise or signal interference and attenuation variations.

For benefit of those not familiar with operation of several transmitters through common tuning and coupling equipment, it might have been helpful if the author had covered this subject more fully.

The title of the paper indicates that the equipment is suitable for both telemetering and load control. However, the paper describes the application of the equipment for telemetering. Some mention of application for the transmission of load control signals might have been desirable, especially if modifications are made in the equipment when it is used for this purpose.

R. W. Beckwith: The operation of several transmitters or receivers involves no particular problems since all transmitters or receivers are merely tied in parallel and then treated in all tuning and coupling circuits as though there was only one transmitter or receiver.

A somewhat special, but at the same time simple and straightforward, tuning procedure for the individual parallel connected transmitters has been worked out. The individual receivers are tuned exactly as if the other receivers were not present.

This equipment is already in use by the Tennessee Valley Authority for the transmission of a load control reading, in which case the reading is merely an integrated telemeter quantity. A load control application may require the transmission of both a raise and a lower impulse, and if so, requires special consideration.

A question has been brought up concerning the type of crystals used. These are of various cuts depending upon frequency. The choice is governed by the desire to obtain small size and at the same time good temperature coefficient. These crystals are silver plated and mounted in an octal metal tube shell. The shell is filled with dry nitrogen and hermetically sealed. This mounting is probably the most stable type in general use today.

Channels for Operation of Supervisory Control Equipment

W. A. DERR
MEMBER AIEE

M. J. BROWN
MEMBER AIEE

A SUPERVISORY control channel consists of a transmission medium and channel terminal equipment. The existing installations of supervisory control employ metallic circuits as the transmission medium. The metallic circuits in use are either telephone line wires or power lines. For operation over telephone line wires, pulses of direct current are generally used to transmit the desired information. When a power line is the transmission medium for operation of supervisory control equipment, a power-line carrier frequency or subcarrier is utilized.

Consideration is now being given to a new type of supervisory control channel making use of space as a channel transmission medium. The advent of micro-wave radio equipment has renewed interest in the use of the hitherto impractical radio channel for operation of supervisory control equipment.

Operation by d-c pulses may be effected over open construction telephone lines or telephone cable wires, either of which may be privately owned or leased. The service record of this type of operation has been exceptionally good through a period of 25 years. Cable wires are less susceptible to lightning strokes, induced voltages between wires, and crossovers with high tension lines, and are therefore preferable to open-wire lines. However, very effective protective equipment for open-wire lines is in common use for the protection of equipment and personnel.

A power-line carrier channel is used usually where the cost of the power-line carrier terminal equipment is less than the cost of establishing a telephone line. There are also instances where an economic advantage can be obtained by having supervisory control share a power-line carrier channel with other services. A very satisfactory operating record of supervisory control over power-line carrier channels has been established during the past 12 years.

While there are no commercial installations to date, the practicability of the use of micro-wave radio channels for the operation of supervisory control equipment has been established. Promise is held for this type of channel if enabling and protective government regulations are established.

General

Supervisory control communicates orders from a dispatcher to equipment at a remote station, which in turn acknowledges these orders and verifies their execution.

The interconnecting means between the dispatcher and remote stations is of the utmost importance to a supervisory control system, just as it is to any communication system. The interconnecting means for transmitting intelligence between two or more locations for any communication service constitutes a channel.

While supervisory control may employ any conceivable type of channel, in practice it is found that a simple system of keying electric potential into pulses is the most acceptable. A system of this type uses a simple transmitting relay and a simple receiving relay at each station. In the basic arrangement of this system, d-c operation over two metallic conductors is employed.

Where the metallic circuit is used for other services besides supervisory control, then the system used must provide non-interfering channels over the metallic circuit. Such noninterfering channels can be established by using d-c impulses for supervisory control with a-c signals for the other services. Where the metallic conductors are power lines and the major service is the transmission of power frequency, d-c impulses for supervisory control are impractical. In these cases, the supervisory control signals are transmitted as a-c pulses at a power-line carrier frequency.

An important extension of the idea of pulsing alternating voltage, is the use of space radio as a channel between the supervisory control stations.

A channel consists of a transmission medium and terminal equipment. When operation is by means of d-c impulses over a metallic circuit, the transmission medium is the pair of wires and the channel terminal equipment consists solely of protective equipment. When operation is by means of a carrier frequency on a power line, the transmission medium is the power line and the channel terminal equipment consists of the carrier frequency generating and receiving equipment as well as the necessary components for introducing the carrier frequencies to the transmission line. When operation is by means of space radio equipment, the transmission medium is the ether and the channel terminal equipment consists of the radio frequency generating and receiving equipment as well as the necessary antennas. Figure 1 indicates the transmission medium and the channel terminal equipment required to establish a supervisory control channel on a pair of telephone wires, on a power line, and through space.

Paper 48-298, recommended by the AIEE substation committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted May 5, 1948; made available for printing September 10, 1948.

W. A. Derr and M. J. Brown are both with the switchboard engineering department of the Westinghouse Electric Corporation, East Pittsburgh, Pa.

The authors express appreciation for use of information on the New York, New Haven and Hartford Railroad Company micro-wave tests to Sidney Withington and H. P. Brown of the New York, New Haven and Hartford Railroad Company; and to M. E. Reagan and D. R. Tashjian of Westinghouse Electric Corporation.

Supervisory control terminal equipment is essentially the same regardless of the type of channel employed. Thus, in choosing a channel means for operation of supervisory control equipment, the choice should be governed primarily by a comparison of the possible channel means themselves. The following factors should be taken into account in determining the most suitable channel means for a given application.

1. Reliability.
2. Simplicity.
3. Cost of installation.
4. Cost of maintenance.
5. Privacy.
6. Freedom from interference.
7. Freedom from legal regulations.

Telephone Line Wires

More than 95 per cent of all of the existing installations of supervisory control equipment operate over telephone-line wires. These installations operate over open construction telephone lines or wires in telephone cables, some of which are leased from telephone companies and some of which are privately owned. Supervisory control equipment as manufactured today operates over a single pair of conductors.

Privately Owned Cable Wires

When it can be economically justified, the use of a twisted pair of cable wires for the transmission of d-c supervisory control impulses is recommended. The use of a pair of cable wires can often be justified if other pairs in the cable can be assigned to other functions such as pilot wire relaying. The use of d-c impulses minimizes interference with other services and places no practical limitation on the length of cable over which control can be provided. An installation is in operation over 125 miles of number 16 gauge cable wires. Lead-sheathed cable either buried in the ground or whose sheath is frequently grounded is preferred since it inherently has a high degree of protection against lightning and electrostatic induction.

Cable wires are subject to the following disturbing voltages:

1. Induction from power lines.
2. Lightning and other surges.
3. Elevation of station ground potential.

When a twisted pair of cable wires is employed, no appreciable voltage will appear between the wires for any of the disturbing voltages listed. Thus, the only thing which must be considered is the voltage to ground which can appear on both wires.

Figure 1. Diagram indicating channel transmission medium and channel terminal equipment for supervisory control operation

(a) telephone line wires, (b) power-line carrier, (c) space radio

On the usual installation of supervisory control equipment, voltage will only appear on the cable wires momentarily for any of these disturbing voltage conditions, since there will only be an appreciable amount of induced voltage and a difference in ground potential during adjacent or nearby transmission line faults. Thus, the duration of the disturbing voltage will never be greater than several seconds even when slow-speed relaying is involved on the transmission lines. There is usually no objection to having the supervisory control channel momentarily inoperative during power-line fault conditions. Hence, protection of the supervisory control equipment at each station is normally provided by a gas-filled protector tube which will break down between 350 and 550 volts rms and which will discharge currents of the order of 50 amperes for two seconds.[3] The protector tubes are connected as shown in Figure 2. The protector tube has an average arc drop of 20 to 30 volts of direct current. The supervisory control circuits are arranged so that the arc is cleared and the line returned to normal as soon as the disturbing voltage disappears.

When protector tubes are applied to cable wires, they should be connected to all wires in the cable which are used for any service and the unused con-

Figure 2. Usual protection for privately owned cable wires

ductors should be grounded unless it is known that the voltage which may appear between the wires and ground is less than the rating of the insulation between wires or between the wires and the sheath.

When supervisory control is applied for the control of a-c electrified railway substations, additional protective equipment may be required, since the single-phase ground-return system induces voltage in the cable wires from the flow of load current, under conditions of stub end feed. If the control cable is in close enough proximity to the catenary wires to induce voltages of several hundred volts or more in the cable wires, protective equipment should be provided to distribute the voltage in such a manner as to maintain the voltage to ground which can appear on the supervisory control equipment to a low value.

Simple resistor-type drainage equipment can be used in some cases, as shown in Figure 3 (a). The resistance values of the resistors are determined by the maximum induced voltage which can result from load current, the number of stations being operated on a single pair of wires, and the resistance of the wires. The induced voltage is given a path to ground through the resistors, the voltage thus being dissipated as resistance drops. The value of the resistors connected from the wires to ground must be such that the amount of voltage which can appear between the wires and ground for maximum load conditions is less than the breakdown voltage of the protector tube. The padding resistors in the line circuit may or may not be required depending on the resistance of the wires.

The use of a 2-winding neutralizing transformer is usually preferred for distributing continuously induced voltage on cable wires used for operation of supervisory control equipment.[3] The neutralizing transformers are connected to the cable wires as shown in Figure 3 (b). The two microfarad capacitors connected from the equipment side of the neutralizing transformers to ground provide an excitation path for the neutralizing transformer. The two windings of the neutralizing transformer are wound in the same direction on the core, so that currents which flow in the same direction in the line wires encounter exciting impedance, whereas the supervisory control impulses encounter only the leakage impedance. The exciting impedance of these neutralizing transformers can be made as high as 100,000 ohms at 60 cycles with only 160 ohms added to the loop resistance of the wires. Two microfarad grounding capacitors as indicated in Figure 3 (b), have a parallel impedance of 663 ohms at 60 cycles and limit the voltage on the supervisory control equipment to about 0.66 per cent of one-half of the induced voltage, assuming that one-half of the voltage is impressed across each neutralizing transformer. Thus, the high voltage appears from the line side of the neutralizing transformers to ground and a low voltage appears on the equipment side of the neutralizing transformers to ground.

When neutralizing transformers are applied to a pair of cable wires, lightning arresters may be required on the line side of the neutralizing transformers if the wires can be subjected to disturbing voltages of a higher magnitude than the maximum induced voltage for which the circuit must remain operative. The lightning arresters must be coordinated with the insulation rating of the cable. Also, if neutralizing transformers are not applied to all of the wires in a cable, the insulation between wires of the cable must be sufficient to withstand the voltage difference which can appear between the wires with neutralizing transformers and the wires without neutralizing transformers.

Privately Owned Open Construction Telephone Lines

Open construction telephone lines can be subjected to the following disturbing voltages:

1. Induction from power lines.
2. Lightning and other surges.
3. Elevation of station ground potential.
4. Direct crosses with high-voltage lines.

Where possible, it is desirable to have the telephone line located remote from any transmission line to eliminate the possibility of direct crosses with high-voltage lines and to reduce the magnitude of induced voltage. With open construction lines, there is the possibility of induced voltage between the line wires as well as of induced voltage to ground. The telephone wires must be transposed at frequent intervals to keep to a minimum the induced voltage between line wires resulting from load current in nearby transmission lines. Close spacing of the telephone wires also helps keep the voltage between wires to a low value.

If the telephone line wires are located so that there is no possibility of contact with high-tension lines, and if the induced voltage which can appear to ground is low for transmission line load currents, protection can be provided by a gas filled protector tube at each supervisory control location as described for the protection of cable wires. Lightning arresters can also be used as back-up protection for the protector tubes.

Since the control lines usually run

Figure 3

Figure 4

(a) Protection of open construction telephone lines using line fuses

(b) Protection of open construction telephone lines using neutralizing transformers

(c) Protection of open construction telephone lines using neutralizing transformers and line fuses

between power stations, economics often dictate they be strung on the same pole. To protect the equipment and personnel when there is a possibility of direct contact with a power line, additional protective equipment should be used. Minimum additional protective equipment can be added if permanent interruption of the supervisory control circuit is warranted for a direct contact with a high-tension line. The additional minimum protective equipment in this case consists of high-tension fuses which interrupt the line circuit on the current which flows to ground through the protector tube when there is a contact with a power line. The rating of the fuse should be such that the fuse will not blow on the current which can momentarily flow as a result of induced voltage or difference in ground potential. Padding resistors are sometimes necessary in the line circuit to obtain discrimination between the current which can flow for a direct contact with a power line and the current which can flow as a result of induced voltage or difference in ground potential. The arrangement is shown in Figure 4 (a).

Figure 4 (b) shows protective equipment for open construction line wires strung on the same poles as high-tension lines, which provides the same degree of protection for personnel and equipment as could be provided if an insulating transformer were to be used instead of a neutralizing transformer. The use of a neutralizing transformer permits operation by d-c impulses.

With the protective arrangement shown in Figure 4 (b), the voltage which can appear on the equipment side of the neutralizing transformer is limited by the high impedance of the neutralizing transformer to other than circulating current, with respect to the impedance of the drainage capacitors. The protector tube on the equipment side of the neutralizing transformer limits the voltage on the equipment to between 350 and 550 volts rms in the case of direct contact with high-tension lines. For any disturbing voltage condition, a high voltage is built up on the line side of the neutralizing transformer. If this voltage is high enough, the gaps on the line side of the neutralizing transformer break down. When only one winding of the neutralizing transformer has voltage impressed on it, it presents a high impedance. Thus, in the event of contact of one of the supervisory control line wires with a power line, a high voltage immediately appears to ground from the line side of the neutralizing transformer winding in the wire contacted. The gap to ground, shown in Figure 4 (b), breaks down, with the current flow to ground only being limited by the resistance of the line wire. The gaps on the line side of the neutralizing transformer should have a rating which will carry the flow of current which results from a direct contact with a power line for a considerable length of time. Normally, the time which this current flows is not more than several seconds due to the opening of circuit breakers on the power line.

If it is desired to provide the maximum protection including a fuse to interrupt the line circuit in the event of a direct contact with a high tension line, an arrangement as shown in Figure 4 (c) can be used. With this arrangement, the fuse rating must be such that it will interrupt the circuit on the current which will flow through the gaps between the neutralizing transformer and the fuses, when there is a direct contact with a high tension line. When the fuse interrupts the circuit, the high voltage is transferred to the gap on the line side of the fuse. This gap then breaks down and effectively grounds the line wire for as long as the power-line voltage remains on the supervisory control-line wire.

The gaps shown in Figures 4 (b)

Figure 5. Components required to provide line-to-ground carrier channel for control of one station

and 4 (c) can be either carbon or metallic. There is an advantage in the use of carbon gaps, since there is no tendency to weld and thus permanently short circuit the line to ground, or cause a short circuit between wires.

Leased Telephone Channels

A large number of supervisory control installations are operated over channels leased from telephone companies. The channel leased from a telephone company may consist of a cable pair, a pair of open construction wires, a phantom circuit, or a combination of these types of circuits. Protective equipment similar to that provided for commercial telephone circuits is ordinarily provided for leased channels by the telephone companies.

Supervisory control equipment which operates by means of d-c coded impulses, is designed to be well within the voltage and current limitations imposed by the telephone companies. A maximum of 135 volts of direct current to ground and 270 volts of direct current between the telephone wires may be used. The maximum permissible current is 0.35 ampere.

When audio frequencies are employed for continuous telemetering in conjunction with supervisory control, the voltage limitations shown in Table I are usually imposed. The voltage values may have to be substantially reduced in cases where the circuit or terminal equipment is unbalanced to ground.

Power-Line Carrier Channels

In operating supervisory control equipment over a power-line carrier channel, the carrier transmitters are keyed to transmit the coded impulses and carrier receiver relays pass along the impulses to the supervisory control equipment itself. The supervisory control terminal equipment for operation on a power-line carrier channel is essentially the same as equipment which is employed on telephone-line wires. The carrier channel merely constitutes a different means for transmitting and receiving the coded impulses. However, where selective telemetering is required, some of the types of telemetering equipment which can be used in conjunction with supervisory control equipment operated over telephone-line wires, cannot be used on carrier channels.

Supervisory control equipment which operates by means of a single type of coded impulse and hence requires a single receiving element, can be operated over the same type of carrier channel which is used for protective relaying.[4,5] When no other service besides supervisory control is provided on a carrier channel, the transmitters and receivers at all stations are operated on the same frequency and no modulation by audio tone equipment is required.

Carrier channels can be employed over relatively long distances providing the losses are not too great and the noise level is not too high.[6] Therefore, a carrier channel can often be advantageously employed where long distances are involved. One supervisory control system has been in operation for more than ten years on a power-line carrier channel over a distance of 270 miles.[7,8]

Carrier on a power line provides a very reliable channel. However, since carrier for supervisory control operation is usually operated from one phase-to-ground, a ground on the phase to which the carrier is coupled may make the equipment inoperative. In some instances, greater reliability can be obtained by providing alternate routes for the carrier signals.

Figure 5 shows in diagrammatic form the components required to provide a line-to-ground carrier channel for operation of supervisory control for the control of a remote station. If there are any spur lines tapped from the lines over which the carrier operates, it is usually desirable and sometimes necessary to provide line traps at the junction of these spur lines as indicated in Figure 5.

Up until fairly recently, power line carrier channels were limited to the 50- to 150-kc range. This range has now been extended to 300 kc which has helped considerably in the finding of suitable channel space for the various functions for which power-line carrier has been employed. Also, the use of single side-band carrier channels makes possible a greater number of noninter-

Figure 6. Micro-wave antennas at Darien for tests on New York, New Haven and Hartford Railroad Company property

Figure 7. View of micro-wave transmitter receiver cabinet used in tests on property of New York, New Haven and Hartford Railroad Company

fering channels.[9] However, in some locations where large numbers of carrier channels have been installed, the choice of suitable additional channels is still a problem, since it is difficult to limit a carrier frequency to a desired portion of an interconnected system.

Supervisory control can sometimes be combined with other functions for operation on the same carrier channel.[10] This sometimes requires that the supervisory control equipment be operated on a single audio tone modulating the carrier frequency.[11] When such combination can be made a saving in cost results and there may also be a reduction in the total number of different carrier frequencies required. However, there are numerous problems in making such combined applications and each case usually requires individual study.

There are some instances in which the power line is not available at the desired location for the dispatching office end of a supervisory control system. In these instances the channel must be extended from the carrier channel to the dispatching office by means of telephone-line wires. This necessitates delivering the supervisory impulses from the carrier channel to the telephone wires and vice versa. The provisions for delivering the impulses and the requirements of the telephone-line wire circuit are dependent on whether a single or a 2-frequency carrier channel is used, on the length of the telephone wire circuit, and on whether other functions besides supervisory control are provided on the carrier channel.

Space Radio Channels

Consideration has been given for a long period of time to the possibility of using space radio channels for the operation of supervisory control equipment. Development of micro-wave equipment with its directional and thus less interfering feature has opened the door to the possibility of using space radio channels for the operation of supervisory control if legal conditions permit. The first field tests to determine the feasibility of using micro-wave radio channels for operation of supervisory control equipment were made in 1943. An installation of coded d-c impulse-type supervisory control equipment has been in operation over a pair of cable wires between the Cos Cob power plant and the Darien substation of the New York, New Haven and Hartford Railroad since 1939. The two stations are 6.25 air line miles apart. For these tests, the supervisory control terminal equipment was disconnected from the line wires and temporarily connected to micro-wave radio transmitter-receiver equipment for a period of a month.

Two antennas were mounted at each station, one for transmitting and one for receiving. Each antenna consisted of four full-wave dipoles. At the Cos Cob power plant, the antennas were placed on the roof of a boiler house, approximately 90 feet above mean sea level. At Darien substation, the antennas were mounted on wooden poles on top of an anchor-bridge approximately 108 feet above mean sea level. Figure 6 shows the two antennas mounted at Darien substation. Although the terrain did not permit "line-of-sight" transmission, satisfactory operation was obtained.

At Cos Cob, the transmitter-receiver cabinet was mounted adjacent to the antenna on the roof, with the keying, receiver, and power leads carried to the supervisory control equipment in the control tower some 300 feet away. At Darien, the transmitter-receiver cabinet was located in the substation building and connected to the antennas through approximately 75 feet of coaxial cable. Figure 7 shows a view of the transmitter-receiver cabinet used at each location.

A frequency of approximately 525 megacycles was used. Operation was tried by keying the micro-wave frequency direct and by keying a modulating audio frequency. Both methods of operation were satisfactory.

Supervisory control equipment has been manufactured for the United States Coast Guard for the control of an unattended lightship from the shore, by means of space radio equipment. The supervisory control equipment will be used to start and stop Diesel generators, operate beacon signals, and so forth.

A separate radio frequency will be used for the transmission of supervisory control impulses in each direction. A frequency of 165.375 megacycles will be used to transmit impulses from the shore to the lightship and a frequency of 171.375 megacycles will be used to transmit impulses from the lightship to the dispatching office located on the shore. The supervisory control equipment will operate by keying tone equipment which will frequency modulate the radio transmitter output.

Figure 8 shows the lightship which will be controlled. A towing vessel is partly visible behind the lightship.

The Federal Communication Commission has not as yet allocated any micro-wave radio bands for operation of supervisory control equipment on a permanent basis. However, the band from 952 to 960 megacycles as well as other bands up to frequencies as high as 6,000 megacycles are now available for experimental installations. If experimental usage is made there is a possibility that these bands may be allocated on a permanent basis.

The band from 952 to 960 megacycles is particularly appealing since conventional tubes and circuits can be used in manufacturing equipment for this band of frequencies.

Conclusions

Supervisory control terminal equipment which operates by coding a single type of impulse can be fundamentally the same regardless of the channel employed. Therefore, the reliability of such a supervisory control system is largely determined by the reliability of the channel transmission medium and the channel terminal equipment. Telephone-line wires and power-line carrier channels have been accepted through the years as reliable channel means.

Micro-wave radio equipment for operation of supervisory control equipment may be made commercially available in the near future. There is every reason to believe that this will be as reliable as the channel means previously used.

If more than one reliable channel is available for a given application, the

Figure 8. View of United States Coast Guard light ship which will be controlled by supervisory control equipment operating over space radio channel

choice is governed by the cost of the channel terminal equipment plus the cost of the channel transmission medium. The expected cost of replacement parts and cost of maintenance should also be considered.

Legal restrictions, privacy and freedom from interference are other factors which warrant consideration.

The next several years will prove interesting as regards the use of microwave channels for the transmission of supervisory control impulses, since this period will probably determine whether or not this channel means comes into as general usage as telephone-line wires and power-line carrier channels. Experience will indicate the limitations of operation without repeat stations as governed by the intervening terrain.

Short Time Ratings of Diesel-Electric Locomotives

D. R. CAMPBELL
NONMEMBER AIEE

T. J. WOODS
ASSOCIATE AIEE

IN THE PAST quarter century, the Diesel-powered locomotive has developed into one of the most efficient and economical forms of motive power available to railway and industrial users. It is a versatile unit, performing equally well in all types of service, ranging from 100 horsepower lightweight units used in intra-plant switching to huge 8,000 horsepower locomotives for mainline freight service.

This versatility is due largely to the d-c electric transmission system interposed between the prime mover and the driving wheels. The Diesel engine is a relatively constant torque machine having little torque variation between idling and full speed. On the other hand, the torque required at the driving wheels of a locomotive varies from the maximum required at starting to low values at high speed, corresponding to the available engine horsepower.

The transmission system consisting of generators, series type motors, and control, provides an effective means of changing the constant torque of the prime mover to the everchanging values of torque required at the rims of the driving wheels. To date, no other method of power transmission, and torque conversion can equal the electric system in reliability, economy of maintenance, and effectiveness.

The use of the Diesel-electric locomotive brought with it the problem of determining the maximum trailing tonnage the unit is capable of pulling over a given section of a railroad. With the reciprocating steam locomotive, this is a simple problem. The steam locomotive can take the maximum load it is capable of starting and hauling over a given profile without damage to its component parts. Too great a load will result in stalling on the ruling grade, or inability to start the train, however, no harm will result. Where running time is the determining factor, the train will be loaded with the number of cars it is capable of hauling to its destination within the scheduled time.

In the case of the Diesel-electric locomotive, the problem is more difficult. The ability of the electric transmission system to take loads in excess of the continuous rating invites the possibility of dangerously overloading the electric propulsion equipment in order to move a desired tonnage. The continuous rating of a Diesel-electric locomotive is the tractive force developed at the rail, expressed in pounds, for any period of time without the temperature rise of the generator or motors exceeding 120 degrees centigrade on the armature, or 130 degrees centigrade on the fields, as measured by resistance. This continuous rating, however, gives little indication of the tonnage which can be handled on short sections of heavy grade; therefore, various methods have been devised to determine the maximum tonnages which may be handled for short times, thus utilizing the electric equipment to its fullest capacity. The ultimate of electric loading would be an everchanging load to compensate for the changing grade, track conditions, and so forth, to give a constant temperature at the maximum rated temperature rise.

While the maximum motor current is limited by the maximum adhesion between the driving wheels and rail which may vary from 10 to about 35 per cent, depending on track conditions, the continuous current is limited by the temperature rise of the electric equipment. The temperature of traction motors is difficult to measure in service as it means stopping the locomotive at some point and applying temperature measuring devices. The readings then have to be extrapolated to determine the cooling that took place between power cutoff and the time the first temperature reading was taken. This method is unacceptable in normal service and is restricted to special testing of locomotives. Therefore, it is of little practical value in determining locomotive ratings. To date, there is no practical instrument to indicate the temperature of the electric equipment to the locomotive engineer. Even such an instrument would not completely solve the problem. It is desirable to know at the starting point what tonnage the locomotive is capable of hauling over the profile. An accurate temperature indicating device will inform the operator when to reduce the load on the electric apparatus. However, at this point, a stop may be impractical from the railroad's point of view.

There are, in general, two types of service performed by locomotives in railway work. These are classified as switching and road service. They may be further classified as yard, terminal, and hump switching, road transfer, road freight, and passenger service. Because of the difference in the duty cycle for road and switching work, a different method is used in each case to determine the capability of the locomotive in that particular service. The duty cycle imposed on the electric equipment in normal switching service is not usually of a severe nature, especially in industrial work. It usually consists of accelerating a string of cars to about ten miles per hour, coasting a short distance, then braking to a stop. Thus, current is flowing through the traction motors for only a

* Limited by 30 per cent adhesion; 5 pounds per ton for acceleration.

These trailing loads are based on the power plant operating at full speed and horsepower. These tonnages cannot be hauled if the locomotive has been operating up to continuous temperature limits. A 15-minute cooling period must be interposed before the overload operation is started if the equipment has been operating up to AIEE temperature limits.

(Figures shown are Tons Trailing Load)

short time. Experience has shown that a continuous tractive force rating of approximately 13 to 15 per cent of the weight on drivers is sufficient to handle typical switching operations without danger of overheating the electric equipment. Tonnage charts may be prepared for switching service for runs of different lengths and on various grades. A typical tonnage chart is shown in Table I. This covers a 650-horsepower 80-ton locomotive and shows the length of run and permissible trailing tonnage for a range of ruling grades. The tonnage charts are based on a 15-minute cooling period from the maximum temperature rise preceding the application of the overload. Table I was derived from the curves of Figure 1. The tractive force-time curve is plotted from data obtained from motor tests and the tractive force-speed curve is part of the combined performance curve, Figure 2. The distance curve, thus, shows the tractive force which can be maintained for a given distance. From this the trailing tonnage, which can be hauled for a given distance after the traction equipment has

Figure 1. Curves for determination of tonnage tabulation

cooled for 15 minutes, is calculated by the following equation:

$$W_t = \frac{TF}{TR + 20G} - 80$$

where

W_t = weight of trailing train, in tons.
TF = tractive force, in pounds, available for a fixed distance.
G = grade, in per cent.
TR = train resistance, in pounds per ton. This varies with the weight, number of wheels, and so forth, of each car. Eight pounds per ton has been assumed as an average, for the entire train.

Road service is vastly different from

Figure 2. Combined performance curve of 650 horsepower locomotive

switching service as the Diesel engines may be loaded to maximum output for acceleration and held at full rated load for a considerable length of time. This service imposes a more severe duty on the Diesel engine and electric equipment than normal switching service. With a continuous tractive force rating of 13 to 15 per cent of the weight on drivers for passenger service, and 18 to 20 per cent for freight service, the electrical maintenance should hold at a reasonable level. As road locomotives usually operate on varying profiles, the tonnage rating may be determined by use of heating and cooling curves of traction generators and motors. This is done by assuming a tonnage somewhat greater than can be handled at the continuous rating on the ruling grade, and then calculating the temperature rise of the propulsion equipment in pulling the train over this peak grade.

As an example, assume a 1,500-horsepower locomotive weighing 125 tons operating on a rolling profile such as shown in Figure 3 with a trailing load of 2,500 tons. At point "A", the equipment is assumed to be 40 degrees above the ambient after doing general switching work prior to leaving the terminal. The tractive force required to handle the train on the grade section from "A" to "B" is calculated as follows:

Grade resistance = 0.1 × 20 pounds per ton = 2 pounds per ton
Train resistance = 5.7 pounds per ton (Davis train resistance of 40-ton car at 23 miles per hour)
Total tractive force required = (2 + 5.7) × (2,500 + 125) = 20,200 pounds

From the performance curve of this locomotive, Figure 4, a tractive force of 20,200 pounds is developed at 23.3 miles per hour and at 79.4 per cent current on FS-2. At this speed, neglecting acceleration, the locomotive will reach point "B" in 25.8 minutes. The heating and cooling curve, Figure 5, shows 9.5 minutes as the intersection of the 40 degree rise ordinate and the 79.4 per cent current curve, therefore, the time at "B" is 9.5 + 25.8 = 35.3 minute abscissa and the 79.4 per cent current curve. The resulting temperature rise will be 81 degrees. The tractive force

Figure 3. Typical railroad profile

Figure 4. Combined performance curve 1,500 horsepower locomotive

Figure 5. Heating and cooling curves for electric equipment on 1,500 horsepower Diesel-electric locomotive

required from "B" to "C," neglecting deceleration is:

Grade resistance $= 0.33 \times 20 = 6.6$ pounds per ton

Train resistance $= 5.2$ pounds per ton (Davis train resistance of 40-ton car at 16 miles per hour)

Total tractive force required $= (6.6 + 5.2) \times (2{,}500 + 125) = 31{,}000$ pounds

From Figure 4, 31,000 pounds tractive force is developed at 15.2 miles per hour and 79.5 per cent current on FS-1. At 15.2 miles per hour, the time from "B" to "C" is 7.9 minutes. Starting at 81 degrees, Figure 5, 7.9 minutes on 79.5 per cent current will increase the temperature rise to 85 degrees. On section "C" to "D," no power is required; and neglecting acceleration, assume train runs at the speed limit of 40 miles per hour for 1.5 minutes. Again, refer to Figure 5 and the no load cooling curve which shows 1.5 minutes cooling reduces the temperature to 80 degrees rise. The tractive force required from "D" to "E," neglecting deceleration, is:

Grade resistance $= 0.73 \times 20 = 14.6$ pounds per ton

Train resistance $= 4.8$ pounds per ton (Davis train resistance of 40-ton car about 9 miles per hour)

Total tractive force required $= (14.6 + 4.8) \times (2{,}500 + 125) = 51{,}000$ pounds

From Figure 4, 51,000 pounds tractive force is developed at 8.8 miles per hour and 114.5 per cent current on FS-1. At 8.8 miles per hour, the time from "C" to "D" is 27.3 minutes. Since the 114.5 per cent current line starting at 80 degrees crosses the 120 degrees temperature rise in 14 minutes, in place of the 27.3 minutes required, the load must be reduced to protect the electric equipment from early failure. The same calculations must be made again to check the temperature rise with a smaller load. It will be found that a tonnage rating of approximately 2,200 tons will apply on this profile. From the foregoing, the heating and cooling curve method is evidently a cut and dry proposition but gives results sufficiently accurate for general application studies.

It is to be noted that momentum, acceleration, and deceleration were not considered in the preceding example. In going from a negative to a positive grade, the train will gradually slow down until a balancing speed is reached after which a constant velocity will be maintained up the grade. Neglecting momentum and using balancing speeds will result in a slightly pessimistic answer; because of the many variables involved, this is desirable.

Under certain conditions, it may be found necessary to consider momentum in negotiating short sections of heavy grades, in which case a continuous speed-time curve will serve to determine the limiting tonnages.

A third method of calculating the severity of a service is the rms method as used in industrial applications. This serves well where the duty cycle is of short duration and is of a repetitious nature. However, in a transportation service where the locomotive may be subjected to an overload on one severe grade until the maximum temperature rise is reached, the rms method does not give an accurate indication of the severity of the service and is, therefore, not of great value in calculating locomotive tonnage ratings in mainline railway service.

Although Diesel-electric locomotives have now been in general use for almost a quarter of a century, no standard methods have been adopted to determine the hauling capacity of a Diesel-electric locomotive for the various services it may perform. It is recognized that the thermal capacity inherent in electric apparatus greatly increases the value of the electrically-propelled vehicle, and acceptable methods of evaluating this characteristic should be available for general use. The methods presented herein are offered as a possible solution for determining tonnage hauling capacities or as a foundation on which to base a practical system acceptable to all concerned.

No Discussion

The Present Competitive Position of Coal, Residual Oil, Diesel Oil, and Electricity as Energy Sources for Motive Power Operation in the Pacific Northwest

T. M. C. MARTIN
ASSOCIATE AIEE

IN the Pacific northwest as in other regions, the Diesel-electric locomotive has become an important factor in main-line railway operations. Before very long it is probable that 50 per cent of all movements will be handled with Diesel-electric motive power. This trend focuses attention upon the relative costs of supplying main-line services with different types of motive power, and particularly upon the most important single element of differential cost, that is, the cost of fuel. The fuel utilized in Diesel-electric locomotives comes from the same fraction of the total petroleum barrel which also is the source of the distillate fuels in heavy demand for highway, farm, residential space heating, and other purposes. Jet-propelled aircraft likewise depend upon middle distillate fuels, a factor of some consequence if another war should transpire. Lately the price of Diesel fuel has begun to reflect these competing uses, although it has not as yet reached a level that exhausts its potentialities for price adjustment, especially in view of the level which residual oil has attained.

Paper 48-301, recommended by the AIEE land transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted August 2, 1948; made available for printing September 9, 1948.

T. M. C. MARTIN is with the Bonneville Power Administration, Portland, Oreg.

There is substantial doubt that further dieselization can be accomplished in the Pacific northwest without paying an excessive premium for the presumed advantages of self-contained motive power units. Based on mid-1948 costs, there appear to be sound reasons for railway managements giving full and immediate consideration to the use of the hydroelectric energy with which the region is endowed. By dieselizing yard and branch-line services, and electrifying main-line operations, these railways can achieve a measure of operating cost stability in an otherwise doubtful situation. This step would require the investment of some new capital, both in fixed plant and rolling stock. Analysis of the available evidence on as objective a basis as possible indicates that such new capital investment could be recovered by operating savings in almost record time.

It is concluded, for example, that an investment of about $6,000,000 to change from Diesel-electric to straight-electric operation on a typical 400-mile division in this region, would produce annual operating savings of about $1,600,000, equal to a little over 25 per cent interest on the new capital invested. This is equivalent to saying that the management is not required to foresee or have faith in the future for more than four years. This fact alone should offer some encouragement in a world that currently permits few longer vistas of things to come.

Rise of Diesel-Electric Motive Power

Early in 1948 one of the principal manufacturers of railway locomotives announced its intention to quit the reciprocating steam locomotive field and concentrate all its effort on the production of other types of motive power, chiefly Diesel electric.

This was but the formal recognition of the existence of a revolution in railway motive power, something which, though it has been denied by many authorities, has been pretty well established by the figures on new locomotives ordered in recent years. Railway Age* has reported a total of 3,064 orders for new Diesel-electric locomotives (domestic use only) in the past two years against but 134 steam locomotives. Purchases of new steam switching units virtually ceased several years ago and the business of steam locomotive building as of today has declined to the point that remaining production is to fill a few "token" orders placed by the so-called "coal roads."

Although purchases of new steam locomotives have declined almost to the vanishing point, there are large numbers of various classes still in service and it is probable that railway motive power rosters will include a substantial representation of steam power for a long time to come. Any realistic view of motive power trends must recognize, however, the significant inroads that Diesel-electric operations have made in comparatively few years in a field dominated for over a century by reciprocating steam power. Interstate Commerce Commission statistics reveal that as of May 1, 1948, there were about 5,000 Diesel-electric locomotives in service on Class I carriers. The distribution by types is given in Table I.

Mere numerical strength is not the best index of the relative importance of Diesel-electric motive power from an operational standpoint. Although on May 1, 1948, Diesel-electric units constituted but 13

* Published weekly in New York.

Table I. Distribution of Locomotives on Class I Railways in the United States as of May, 1948

Classified by Assigned Type of Service[1]

Assigned Service	Total	Type of Locomotive: Steam	Other	Diesel-Electric	Per Cent Diesel-Electric
Yard switching	13,250	9,894	185	3,180	24
Road freight	21,132	19,523	316	1,293	6
Road passenger	6,124	5,084	293	747	12
Total	40,515	34,501	794	5,220	13

1. For all numbered references, see list at end of paper.

per cent of locomotives in service, they were accounting for a much higher proportion of the total work units being performed. Table II shows the relative work load carried by the total Diesel-electric roster during the first four months of this year as reported by the Interstate Commerce Commission. Table III relates the work performance to the numbers of Diesel-electric locomotives in use as of the close of the period, and shows that Diesel motive power is accounting for from 150 to 300 per cent of the work units that would be expected of them purely on the basis of their numerical strength. Part of this splendid performance can be explained on the basis of the relative ages of the locomotives in service but in a very substantial degree the better than average performance of the Diesels is attributable to the superiority of their electric-traction-motor drives.

It can be seen that with better than 2,000 new Diesel-electric locomotives scheduled to be added to rosters this year and with no evidence of any slackening of orders, the time cannot be far distant when 50 per cent of the total work units will be performed by Diesel-electric motive power. It is not the purpose of this paper to discuss in detail the reasons why Diesel-electric units are causing so much absolescence in steam motive power. Previous papers have developed the basic facts regarding the technological changes that are responsible for this trend, and it seems necessary to mention briefly only the cardinal points. In yard switching service, Diesel-electric locomotives possess two important physical advantages:

1. Because all weight is normally motorized they are able to produce higher starting and continuous tractive effort than comparable steam units and therefore they merit larger tonnage ratings.

2. With no fires to clean, ashes to dump, boilers to wash, and with less lost time for assorted other reasons, they have demonstrated a high degree of availability and reliability.

In road passenger service their higher starting and continuous tractive effort, lower center of gravity, freedom from dynamic augment, plus their ability to negotiate long distances between stops for fuel and water, have combined to make them ideally suited to the so-called "streamliner" service. As a road freight locomotive the Diesel-electric excels for a reason that is sometimes overlooked by its most ardent advocates. Largely because of its electrical transmission it is able to develop its full horsepower output at comparatively low speeds and thereby create relatively high continuous tractive efforts at these same low speeds. High continuous tractive effort is in turn the basis for substantial tonnage ratings. And, since all weight is usually on drivers, adhesion is seldom a limiting factor in converting tractive effort into drawbar pull. The Diesel-electric locomotive is thus a good road freight unit, capable of starting and handling relatively high trailing tonnages in comparison to its weight.

Diesel Electrification Versus Straight Electrification

Diesel electrification has become an important characteristic of all main-line railroads in the Pacific northwest. Whether to extend dieselization until it results in the complete elimination of steam facilities is the question of the hour. There is no longer much reasoning opposition to dieselization based on purely operational factors. Most competent observers agree that complete replacement of steam power would enhance the physical plants of the railroads of this region and result in considerable improvement in over-all speeds and tonnages. The question has broadened to one of engineering economics and therefore of alternatives. Assuming that some improvement in motive power was long overdue, it is at least debatable whether the change had to take the form it has. There is some possibility that the changing economics of fuel supply may force a revision of previous estimates of the attractiveness of complete dieselization of main lines and lead engineers to a more careful and open-minded consideration of the merits of coupling Diesel-electrification of yard and branch lines services with straight electrification of main lines.

Electrification advocates recognize that the Diesel-electric locomotive is really an electric locomotive which must carry its power plant with it. The word must is used advisedly, and Diesel-electric proponents could with some logic define a straight-electric locomotive as one that must leave its power plant on the ground. Whether a locomotive carries its generating source with it, or relies upon a central station for its source of energy is a question that involves at once the greatest strengths and the greatest weaknesses of both classes of motive power. Generation of power on the locomotive is an undeniable advantage so far as freeing the locomotive from dependence on a trolley system goes, but it must be recognized that at the same time it restricts the amount of power that can be efficiently produced, and, if the prime mover is a Diesel engine,

Table II. Distribution of Work Units Performed by Diesel-Electric Locomotives in Comparison with Total Work Units Performed by All Classes of Motive Power on Class I Railways in the United States

First Four Months of 1948[2]

Type of Service and Work Unit Employed	Total Work Units for All Classes of Motive Power	Total Work Units Credited to Diesel-Electric Locomotives	Per Cent Diesel-Electric
Yard Switching			
Freight, locomotive hours	18,695,055	6,263,544	34
Passenger, locomotive hours	1,480,780	710,073	48
Total, locomotive hours	20,175,835	6,973,617	35
Road haul			
Freight, thousands of gross ton miles trailing	451,880,341	84,151,283	19
Passenger, passenger train car miles	1,169,298,475	428,598,866	37

Table III. Diesel-Electric Locomotives on Class I Railroads in the United States—Comparison of Work Units Performed in Proportion to Numbers in Service

First Four Months of 1948

Type of Service	Proportion of Diesel-Electric Locomotives to all Locomotives, (From Table I)	Proportion of Total Work Units Credited to Diesel-Electric Locomotives, (From Table II)	Ratio of Work Performed to Proportionate Numbers of Locomotives in Service
Yard switching	24	35	1.46
Road freight	6	19	3.16
Road passenger	13	37	2.85

it limits the primary energy source to petroleum products of the middle distillate variety, the future availability and price of which is surrounded with so much uncertainty.

Although dependence on a trolley limits the scope of activity of a straight-electric locomotive somewhat, it nonetheless frees it from the limitations of relatively small locomotive-borne prime movers and widens the choice of primary energy sources to include coal and residual oil burned in central stations as well as hydroelectric power. In the Pacific northwest, with its substantial present and enormous potential development of hydroelectric power, together with its almost complete lack of petroleum, it is a little difficult to follow the reasoning employed by railroads in becoming more and more involved with a type of main-line motive power from which they can extricate themselves only with difficulty in the event of continuing adverse trends in the supply and price of Diesel fuel.

Comparison of Primary Energy Sources

It is the purpose of this paper to examine briefly the competitive position of coal, residual oil, Diesel oil, and electricity as primary energy sources for main-line railway operations in the Pacific northwest. For convenience of calculation, freight traffic only will be considered. It is of no great value to compare the cost of coal fired on one railroad with residual oil burned on another, or for that matter the cost of the same fuel burned on different divisions of one railroad. Even when the figures employed are expressed on the basis of thousands of gross ton miles, there is seldom a proper recognition of profile differences, relative ages, and efficiencies of locomotives and other operating variables that are the source of gross inconsistencies in the comparisons. It is proposed, therefore, to develop a set of equations that will permit determination of the quantities of each kind of fuel required when the same amount of work is done by different locomotives. The desired equations, to be useful and equitable as between energy sources, must be grounded in the basic physical relationships between force, distance, time, energy, work, power, and so forth, as conditioned by empirical experience in their utilization under actual operating conditions on railroads in this part of the country.

The fundamental physical relationships stated simply are:

$$\text{work} = \text{energy} = \text{distance} \times \text{force} \qquad (1)$$

$$\text{energy} = \text{power} \times \text{time} \qquad (2)$$

The basic units of equations 1 and 2 are feet, pounds, foot pounds, and foot pounds per unit of time. Practically, these units are little used and more familiar practical units will be employed. It is necessary to set up certain equivalents between the electrical, mechanical and thermal units involved. In some instances the equivalents used are not exact but are adequate for the purpose and have been chosen because they simplify calculations.

Energy units

One horsepower hour = 1,980,000 foot pounds

One kilowatt-hour = 2,640,000 foot pounds

Power Units

One horsepower = 33,000 foot pounds per minute
= 1,980,000 foot pounds per hour

One kilowatt = 44,000 foot pounds per minute
= 2,640,000 foot pounds per hour

Thermal Units

One British thermal unit = 780 foot pounds

Let

$KGTM$ = thousands of gross ton miles (including locomotives)

tr = average tractive resistance in pounds per ton

W = total work done against the average tractive resistance (tr) per thousand gross ton miles

Taking

Work = distance × force and converting to practical units (1)

$$W = 1{,}000 \times 5{,}280\ tr$$

Expressing W in heat units

$$W = \frac{1{,}000 \times 5{,}280}{780}\ tr \text{ (in Btu)}$$

$$W = 6{,}800\ tr \text{ (in Btu)} \qquad (3)$$

In using equation 3 it is necessary to assume some approximate heat values of coal, residual oil, and Diesel oil as received, and also to assume reasonable over-all utilization efficiencies. Such utilization efficiencies should be predicated not upon theoretical maximums but rather upon practical, every-day working conditions including recognition of the actual load factors that locomotives will be likely to achieve in main-line service in

Table IV. Illustrating Method of Computing Average Tractive Resistance Over Selected Sections of Railroad

Typical Pacific Northwest Profile

(1) Compensated Gradient, Per Cent	(2) Miles Per Hundred Miles, Per Cent	(3) Tractive Resistance Grade (Pounds/-ton)	(4) Tractive Resistance Traction (Pounds/-ton)	(5) Tractive Resistance Total (Pounds/-ton)	(6) Column (2) × Column (5) (Plus Values)	(6) Column (2) × Column (5) (Minus Values)
0.2	10	4	6	10	100	
0.5	10	10	6	16	100	
1.2	20	24	6	30	600	
1.6	15	32	6	38	570	
−1.4	15	−28	6	−22		−330
−0.9	20	−18	6	−12		−240
−0.5	10	−10	6	− 4		− 40
Total	100				1,430	−610

Average tractive resistance opposing movement = 14.3 pounds per ton. Value of tractive resistance (tr) used in equations 3, 4, 5, 6, and 7.

Average tractive resistance assisting movement = −6.1 pounds per ton. Value of tractive resistance (tr) (actually tractive effort) used in equation 8.

Table V. Comparative Tonnage Ratings—Late Model Steam, Diesel-Electric and Straight-Electric Locomotives

	Type of Locomotive		
	Steam (4-6-6-4)	Diesel-Electric 5,000 Rail HP	Electric 5,000 Rail HP
Total weight of locomotive (tons) (with 2/3 variable supplies)	488	460	360
Continuous tractive effort (pounds)	90,000	112,500	112,500
Total gross tonnage on 1.6 per cent grade (tons)*	2,368	2,960	2,960
Trailing tonnage rating on 1.6 per cent grade (tons) (line 3-line 1)	1,880	2,500	2,600
Ratio gross tons including locomotives to gross tons trailing (line 3 ÷ line 4)	1.26	1.18	1.14

* Line 2 + 38 pounds per ton total tractive resistance on 1.6 per cent grade.

the Pacific northwest. The efficiencies used below agree closely with the experience of a principal northwest railroad as revealed by test data assembled over a considerable number of years. The figures have been rounded off slightly in the interests of easy calculation.

Let

C = pounds of coal per $KGTM$ as burned in reciprocating steam locomotives

R = gallons of residual oil per $KGTM$ as burned in reciprocating steam locomotives

D = gallon of diesel fuel per $KGTM$ as burned in Diesel-electric road locomotives

Assume that the heat contents as received of the respective fuels are

Coal = 12,500 Btu per pound
Residual oil = 150,000 Btu per gallon
Diesel Fuel = 140,000 Btu per gallon

Assume further that the realizable heat contents and over-all utilization thermal efficiencies of these fuels are:

Coal = 680 Btu per pound and 5.4 per cent efficiency
Residual oil = 10,800 Btu per gallon and 7.2 per cent efficiency
Diesel fuel = 34,000 Btu per gallon and 24.3 per cent efficiency

Then substituting in

$$W = 6{,}800\ tr \tag{3}$$

$$C = \frac{6{,}800}{680}\ tr = 10.0\ tr \tag{4}$$

$$R = \frac{6{,}800}{10{,}800}\ tr = 0.63\ tr \tag{5}$$

$$D = \frac{6{,}800}{34{,}000}\ tr = 0.20\ tr \tag{6}$$

Table VI. Fuel and Energy Costs in Cents per Thousand Gross Ton Miles Trailing for Operations over Average Profile Shown in Table IV

	Reciprocating Steam, Coal Burning	Locomotives, Oil Burning	Diesel-Electric Locomotives	Straight-Electric Locomotives
Coal (12,500 Btu per pound as received)				
180 pounds at $4.00 per ton	36.0			
180 pounds at 5.00 per ton	45.0			
180 pounds at 6.00 per ton	54.0			
180 pounds at 7.00 per ton	63.0			
180 pounds at 8.00 per ton	72.0			
Residual oil (6,300,000 Btu per barrel as received)				
11.34 gallons at $1.50 per barrel		40.5		
11.34 gallons at 2.00 per barrel		54.0		
11.34 gallons at 2.50 per barrel		67.5		
11.34 gallons at 3.00 per barrel		81.0		
11.34 gallons at 3.50 per barrel		94.5		
Diesel fuel (140,000 Btu per gallon as received)				
3.37 gallons at 8.0 cents per gallon			27.0	
3.37 gallons at 9.0 cents per gallon			30.3	
3.37 gallons at 10.0 cents per gallon			33.7	
3.37 gallons at 11.0 cents per gallon			37.1	
3.37 gallons at 12.0 cents per gallon			40.4	
Electric energy				
40 kwh at 2.0 mills per kilowatt-hour				8.0
40 kwh at 3.0 mills per kilowatt-hour				12.0
40 kwh at 4.0 mills per kilowatt-hour				16.0
40 kwh at 5.0 mills per kilowatt-hour				20.0
40 kwh at 6.0 mills per kilowatt-hour				24.0

The prevailing Pacific northwest price (mid-1948) of each product is the middle one in each case shown above.

Fuel costs are delivered on locomotives.

Electric energy unit costs are based on deliveries at 3 phase, 60 cycles to railway substations, but quantities shown include transmission losses. Total costs of electric energy are therefore delivered on locomotives.

Equations 4, 5, and 6 are basic equations which will enable computation of the approximate quantity of each class of fuel required per thousand ton miles of operations performed against the same average tractive resistance under the conditions assumed.

In deriving an expression for electric energy requirements additional rotation is required as follows:

$RKWH$ = kilowatt-hours required per thousand gross ton miles as measured at the rail

$SKWH_m$ = kilowatt-hours required per thousand gross ton miles as measured at the substation (motoring)

$SKWH_r$ = kilowatt-hours required per thousand gross ton miles as measured at the substation (regenerating)

e = average over-all electrical efficiency between the rail and 3-phase 60-cycle supply sides of substations where power is delivered to railroads from central station sources.

Further let $e = 2/3$ which is a good realizable figure so far as Pacific northwest main-line railroad electrification is concerned.

Starting with

$$\text{Work} = \text{distance} \times \text{force} \tag{1}$$

$$SKWH_m = \frac{5{,}280 \times 1{,}000 \times 3}{2{,}640{,}000 \times 2} \times tr = 3.0\ tr \tag{7}$$

and

$$SKWH_r = \frac{5{,}280 \times 1{,}000 \times 2}{2{,}640{,}000 \times 3} = 1.3\ tr \tag{8}$$

$SKWH$ is the *net* substation kilowatt-hours per thousand gross ton miles and is obtained by subtracting the regenerative energy of equation 8 from the motoring energy of equation 7, but it should be noted that the tractive resistance (tr) used in the two equations is not the same. The tractive resistance used in equation 7 should be that opposing movement when motoring; whereas that used in equation 8 should be the negative tractive resistance (in reality a tractive force) which results from the downgrade component being greater than the Davis component, when the locomotive is in regeneration.

Comparisons Applicable to the Pacific Northwest

Profiles of Pacific northwest main lines vary in ruggedness, but most roads have ruling grades that reach 2.2 per cent compensated and many miles of all lines are on gradients in excess of 1.0 per cent. Individual analysis is required to determine the average tractive resistance and

Table VII. Comparative First and Operating Costs of Steam, Diesel, and Electric Locomotives, Operating Against Average Pacific Northwest Profiles

Costs Taken on Basis of Individual Locomotives Running 180,000 Miles Per Year and on Price Level Prevailing in Mid-1948

	Type of locomotive: Reciprocating steam				Diesel-electric		Straight-electric	
Primary energy source	Coal		Residual oil		Diesel oil		Hydroelectric energy	
Annual locomotive miles	180,000		180,000		180,000		180,000	
Gross tons trailing per locomotive mile	1,880		1,880		2,500		2,600	
First cost of items not common to all types of motive power								
Steam locomotives at $300,000	$300,000		$300,000					
Diesel-electrics at $125 per RHP					$625,000			
Electrics at $100 per RHP							$500,000	
Assumed pro rata first cost of electrification fixed facilities at 1.25 locomotive costs							$625,000	
Total first costs where differentials occur	$300,000		$300,000		$625,000		$1,125,000	
Operating costs	Per Mile	Per Year	Per Mile	Per Year	Per Mile	Per Year	Per Mile	Per Year
Locomotive repairs	$0.40	$72,000	$0.40	$72,000	$0.60	$108,000	$0.30	$54,000
Locomotive depreciation								
Steam at 3.0 per cent	$0.05	$9,000	$0.05	$9,000				
Diesel at 6.05 per cent					$0.21	$37,800		
Electric at 5.04 per cent							$0.14	$25,200
Electrification overhead costs								
Maintenance							$0.08	$14,400
Depreciation at 3.5 per cent							$0.12	$21,600
Fuel and energy								
339 lbs. of coal at $6.00 per ton	$1.02	$183,600						
21 gals. residual oil at $2.50 per bbl.			$1.25	$225,000				
8.5 gals. Diesel oil at 10 cents per gal.					$0.85	$153,000		
104 kwh electric energy at 4.0 mills per kwh							$0.42	$75,600
Lubrication	$0.01	$1,800	$0.01	$1,800	$0.08	$14,400	$0.01	$1,800
Total annual costs where differentials occur								
Per locomotive mile	$1.48		$1.71		$1.74		$1.07	
Per locomotive year		$266,400		$307,800		$313,200		$192,600
Per thousand gross ton miles trailing	0.787		0.910		0.696		0.412	

fuel and energy requirements over any particular section for which motive power comparisons are desired. To illustrate a suggested method of computing average tractive resistance, Table IV has been prepared. The profile used is believed to be average for the main line railroads of the region. It should be noted that the example in Table IV shows movements in one direction only which is assumed to be representative. Where precise calculations are being made for a specific section, the analysis should be extended to cover movements in both directions. Attention is called to another simplification employed in this analysis. The component of total resistance that is for traction only (Column 4) has been taken as 6.0 pounds per ton straight, in place of employing values varying with speed calculated from the usual Davis formulas. It has been found in actual practice in the northwest that the use of a straight 6.0 pounds per ton leads to conservative results as well as simpler computations. This practice should not be extended to other regions, however, where higher speeds and comparatively easier profiles are encountered. In this region, as the table indicates, the grade component is the one that exerts the major influence on total resistance rather than the Davis component. Finally, the average values of tractive resistance have been computed by expressing the profile in terms of miles per hundred miles, in other words, putting it on a percentage basis.

It is now possible to utilize the average tractive resistance values from Table IV and by substitution into equations 4, 5, 6, 7 and 8, obtain the physical quantities of the various primary energy sources required for the profile assumed.

The proper resistance values are:

14.3 pounds per ton
−6.1 pounds per ton

Taking equations in order

$$C = 10.0\ tr \tag{4}$$

$$C = 10.0 \times 14.3 = 143 \text{ pounds of coal per } KGTM$$

$$R = 0.63\ tr \tag{5}$$

Table VIII. Economic Evaluation of Steam, Diesel, and Electric Motive Power Operating Over Typical 400-Mile Division of Pacific Northwest Main Line

Traffic Consolidated in Terms of Freight Units Only

	Type of Motive Power: Reciprocating Steam		Diesel-Electric,	Straight-Electric,
Primary Energy Source	Coal	Residual oil	Diesel oil	Hydroelectric energy
Total annual traffic (KGTMT)*	5,760,000	5,760,000	5,760,000	5,760,000
First costs based on Table VII				
17.0 steam locomotives	$5,100,000	$5,100,000		
12.8 Diesel locomotives			$8,000,000	
12.3 electric locomotives				$13,837,500
Incremental first costs				
Over steam			$2,900,000	$ 8,737,500
Over Diesel				5,837,500
Annual operating costs based on Table VII				
Cost per KGTMT*	$0.787	$0.910	$0.696	$0.412
Total annual costs (where differentials occur)	$4,533,000	$5,242,000	$4,009,000	$ 2,373,000
Incremental annual savings				
Diesel over steam (coal)			$ 524,000	
Diesel over steam (residual oil)			1,233,000	
Electric over steam (coal)				$ 2,160,000
Electric over steam (residual oil)				2,869,000
Electric over Diesel				1,636,000
Rate of return on incremental investment for:				
Diesel replacing steam (coal)			18.1	
Diesel replacing steam (residual oil)			42.5	
Electric replacing steam (coal)				24.7
Electric replacing steam (residual oil)				32.8
Electric replacing Diesel				28.0

* Per thousand gross ton miles trailing.

$R = 0.63 \times 14.3 = 9.0$ gallons of residual oil per $KGTM$

$D = 0.20\ tr$ (6)

$D = 0.20 \times 14.3 = 2.86$ gallons of Diesel fuel per $KGTM$

$SKWH_m = 3.0\ tr$ (7)

$= 3.0 \times 14.3 = 42.9$ kilowatt-hour per $KGTM$

$SKWH_t = 1.3\ tr$ (8)

$= 1.3 \times (-6.1) = -7.9$ kilowatt-hour per $KGTM$

$SKWH = 42.9 - 7.9 = 35.0$ kilowatt-hour per $KGTM$

It is necessary to recognize that all of the foregoing figures are for thousands of gross ton miles including locomotives. But in moving traffic with different kinds of motive power, the varying weights of locomotives must be compensated for before a valid comparison of the relative quantities of fuel required to handle the trailing loads may be made. On a ruling 1.6 per cent grade, such as comprehended in Table IV, it is possible to arrive at a ratio between gross tons trailing and gross tons including locomotives by the method shown in Table V. This method involves using the characteristics of certain late model locomotives of the three principal types, the examples chosen being representative of motive power now in operation in the Pacific northwest. Applying the ratios of gross tons with and without locomotives developed in Table V to the fuel quantities already calculated yields the following:

$1.26 \times 143 = 180$ pounds of coal per $KGTMT$*

$1.26 \times 9.00 = 11.34$ gallons of residual oil per $KGTMT$

$1.18 \times 2.86 = 3.37$ gallons of Diesel fuel per $KGTMT$

$1.14 \times 35.0 = 40.0$ kilowatt-hours per $KGTMT$

* Indicates thousands of gross ton miles trailing.

In Table VI the quantities of the various primary energy sources expressed per thousand gross ton miles trailing have been extended against a range of unit prices for each source of energy. Five different unit prices are shown for each fuel with the prevailing or mid-1948 Pacific northwest price of each product being given the middle position.

Evaluation of Differential Capital and Operating Costs

In order to have a basis for comparing not only the fuel costs but the other annual costs including fixed charges which vary with the type of motive power, Tables VII and VIII were prepared. In Table VII the fixed and variable costs of all items that are contingent upon the kind of locomotives are shown. Single locomotives utilizing the four principal energy sources are given annual utilizations of 180,000 miles each. The only items of either first or operating cost that are considered are those that are dependent upon type of motive power. Items in which differential costs do not appear are disregarded and in this category are included a great many items which actually do vary with type of motive power but the variances of which are so slight and their calculation so involved that it would not add materially to the accuracy of the final evaluation to include them. The various first and operating costs assumed are believed to be conservative estimates based on actual prevailing price levels applicable to the Pacific northwest in mid-1948.

When all differential costs except return on invested capital are taken into account it is seen that there is a considerable margin in favor of main-line electrification.

Table VIII presents in very brief form a typical analysis of the possible returns on differential capital invested in dieselization and electrification. The method employed is to take a 400-mile operating division having a profile that calls for an average energy expenditure equal to that developed in Table IV and apply the cost figures developed in Table VII. An annual traffic volume expressed in terms of freight units exclusively is assumed equal to 5,760,000 thousands of gross ton miles trailing. This is equivalent to a daily movement of about 20,000 gross tons trailing per day in each direction over the 400-mile division. Utilization of all four locomotives concerned has been assumed at 180,000 miles per year, and no provision made for spare units. The number of each type of locomotive required was determined from the tonnage ratings of Table V.

The return on differential capital investment expended for main-line electrification appears to be very generous indeed and points up the remark made earlier in the paper that railroad managements should be giving serious consideration to using indigenous sources of energy, which in the Pacific northwest means that careful consideration be given main-line electrification employing hydroelectric power.

No Discussion

Handling Suburban Traffic on Steam Railroads

M. L. SLOMAN
NONMEMBER AIEE

SINCE 1940 the volume of suburban commuter traffic on Class I railroads has increased to such an extent that the few railroads heavily engaged in this business have found it difficult to provide the quantity and quality of service demanded by the public. Increased activity in the electric multiple-unit car equipment field is evidence that, given adequate rates, the railroads intend to meet this demand and to obtain their share of new patrons as the commuting public grows larger. Different types of motive power are discussed with respect to their ability to meet or improve the fundamental operating conditions common to all suburban roads. Electric multiple-unit cars have superior operating characteristics and are best suited to provide improved service at minimum expense. The various types of equipment and methods of operation are discussed in regard to the three general classes of existing power systems and voltages used in this service.

Volume and Nature of Traffic

Many years ago the steam railroads of the United States had a virtual monopoly of the suburban traffic. However, the mass production of automobiles and busses combined with better roads, superhighways, and socialized rapid transit systems steadily reduced the volume of this railroad business from 7,000,000,000 commutation passenger miles in 1926 to a low of 4,000,000,000 in 1940. By 1946, the last year for which figures are available, this traffic had increased to almost 6,000,000,000 passenger miles (Figure 1).

While part of this gain was a natural effect of the high rate of employment during the war, a very substantial gain of almost 500,000,000 commutation passenger miles was recorded for the year 1946 over 1945, following the end of both the war and gasoline rationing. This figure is even more significant because many of the big industries were on strike for as long as three months during the year, and new automobiles were on the market for the first time since 1941.

Many causes contributed to this marked increase in suburban traffic, but at least three are outstanding. First, the greatest part of the postwar new home projects are being built in the suburban sections of the large metropolitan areas, and in some cases these communities are 15 to 20 miles from the downtown business center. Second, a fairly high proportion of the downtown business population returned either from the armed forces or from factory jobs in war plants located generally in the outlying sections of the larger cities. Third, the totally inadequate parking facilities in the business districts of all cities have practically forced all commuters and shoppers to seek some means of public transportation. A recent survey indicated that the cost of providing adequate parking facilities is prohibitive, neglecting the tremendous cost for additional street space to handle the huge potential volume of automobile commuter traffic.

Few railroads have enough volume of commuter traffic to warrant large expenditures for improvements. But those that are strategically located for serving the densely populated urban sections of large cities realize that there is a growing demand for this type of service as evidenced by the recent interest in purchases of new equipment. Hence, there is a real need for a review of the operating characteristics of the several types of motive power used so that new equipment may be applied to give the best possible service at the least expense. Of the many factors involved in making the best motive power application for a suburban service, most important and fundamental are the following operating conditions: volume of traffic; maximum schedules; average length of run; maximum speed; maximum train to be handled; and maximum flexibility of motive power.

All suburban operations place a severe burden on the railroad due to the poor load factor which results from the heavy rush-hour peaks occurring for relatively short periods twice each day. These peaks are of such magnitude that the rolling stock required to provide for them is three to six times that for the base load, resulting in very low annual mileage for suburban cars compared with that of cars in through service. As a result of this low annual mileage, the largest item of expense becomes the fixed charges. As a general rule, it is sound economy to expend liberally for equipment which is used continuously, but when it can be used only for short periods, less expenditure is justified. From this standpoint, an electrified multiple-unit operation is

Figure 1. Annual commutation passenger miles for Class I roads (Interstate Commerce Commission reports)

Paper 48-303, recommended by the AIEE land transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted August 11, 1948; made available for printing September 16, 1948.

M. L. SLOMAN is with the industry engineering department of the Westinghouse Electric Corporation, East Pittsburgh, Pa.

ideal, for if the minimum number of motor cars is provided to handle the rush-hour load, a sufficient number will be available for the best possible service during the nonrush hours. The most economical method of operation is the largest possible use of trailers during the rush-hours to reduce the investment for equipment which has a poor load factor, and the use of all motor cars during the nonrush hours to provide the fastest service to attract new patrons. Any increase in traffic during the base period should result in practically net profit since no additional operating expenses are required. As the equipment is available, no additional investment is required; and power is less expensive at these hours, since the load factor is improved and the demand is not increased.

When steam, Diesel, or electric locomotives are used, a large initial investment in motive power is required to handle the rush-hour load, and the fixed charges per mile become burdensome due to the poor utilization of the excess motive power during nonrush hours. However, an eastern road with a large volume of suburban traffic recently placed in service three double-end 2,000 horsepower Diesel-electric locomotives which are regularly assigned to service approximately 320 hours per month in scheduled running times. These locomotives have performed very well and have averaged 10,000 miles per month, but it is doubtful if more will be purchased because additional units could not be utilized to the same extent during the base periods of traffic. On a completely electrified division, there is a field for locomotive-hauled trains on suburban express runs provided the locomotives are available between assignments on through trains.

It is necessary to analyze the schedules and service conditions of the present or proposed new service before the proper accelerating rate and maximum safe speed can be determined. In a recent study of a large suburban operation, the data shown in Table I were recorded although conditions unquestionably will vary on different railroads.

Table I

	Per Cent of all Runs
Runs less than 1 mile*	40.0
Runs from 1.0 to 1.4 miles	23.5
Runs from 1.5 to 1.9 miles	14.3
Runs from 2.0 to 2.9 miles	11.4
Runs from 3.0 to 4.9 miles	7.8
Runs from 5.0 to 9.9 miles	2.2
Runs more than 10 miles	0.8

* A run is taken as the distance from one stop to the next stop, as shown by the timetable.

The average distance for all runs was found to be 1.70 miles, therefore, equipment should be applied with particular emphasis to a 1.70 mile average distance between stops. At the same time ample capacity for the shortest runs and ample speeds for the longest runs also should be provided.

Accelerating Rates

The upper limit of acceleration is approximately 1.5 miles per hour per second (mphps) when 2-motor equipments are used with all cars in the train motorized. For example, to accelerate a 60-ton car with a seated load of seven tons at a rate of 1.5 mphps requires an average tractive effort of 10,200 pounds. The same tractive effort will be delivered with an empty car since automatic current limit control is generally used in multiple-unit service. The weight on drivers with a 2-motor equipment is about 55 per cent, or 66,000 pounds, giving an average nominal adhesion of 15.5 per cent. However, during acceleration the peak tractive effort delivered will be about 15 per cent greater than the average, increasing the nominal adhesion to 17.8 per cent. In addition, there will be a certain amount of weight transfer, bringing the adhesion on the light axle above 20 per cent. Higher rates of acceleration are obtainable for equipment of this type and service, but these can be maintained only under good track conditions such as found in subway service where 2-motor equipment is operated at a 1.75 mphps rate.

Steam and Diesel-electric locomotives are not capable of accelerating trains at a 1.5 mphps rate due to the limitations of their relative adhesive characteristics. Figure 2 shows typical accelerations for 10-car trains. The multiple-unit train will accelerate at a 1.5 mphps rate to 25.5 miles per hour (mph) compared to 0.673 mphps to 8 mph for the Diesel-electric locomotive hauled train and 0.458 mphps to 10 mph for the steam locomotive-hauled train. While the rates will vary for the locomotive-hauled trains depending upon the number of cars, a constant accelerating rate can be maintained with multiple-unit operation regardless of the number of cars in the train, providing of course that either all cars are motorized or that a constant ratio of motor cars to trailers is maintained. On a recent installation of Diesel-electric motive power replacing steam, a considerable reduction in schedules was made due almost entirely to the better accelerating characteristics of the Diesel-electric. On very short runs in local service, a greater improvement in schedule speed is obtained by raising the accelerating rate than by any other method. For this reason, multiple-unit cars will provide faster service, not only because of their high accelerating rates, but also because they will maintain these rates during the rush-hour periods when 10- to 15-car trains are operated. This is not possible with locomotive-hauled trains where the accelerating rate varies inversely with the length or weight of train.

Maximum Safe Speeds

The maximum safe speed for which the motors must be geared is of prime importance in electric or Diesel-electric operation. In the application of new equipment, future operation as well as present schedules must be considered, for operating conditions may change materially during the life of the equipment which experience shows may be as high as 30 years. Gearing for a maximum safe speed of 70 mph with worn wheels represents the desirable minimum, for an extensive suburban operation will comprise a diversified service in which the average length of run per train ranges from one mile or less, to three miles or more. High speeds are not essential for local service where stops are made at every station from the terminal to the end of the run, but they are necessary for the long runs in express service and raise the schedule speed in skip-stop service which is becoming more popular.

Higher Schedule Speed

As most of the new commuter traffic and part of the old is now derived from the new areas which are being built farther from the downtown business section, many railroads now operate trains with stops at every station at the beginning of an inbound run for perhaps seven or eight stops, and then nonstop for distances ranging from five to ten miles to the terminal. Another group of seven or eight adjacent stations will be served by another train in the same manner with a consequent increase in schedule speeds for all trains on the line. Proper scheduling must be done so that all trains can run at high speeds on the express sections of the run, but this is difficult unless trains can run on two tracks in the same direction.

Skip-stop service is a more practical method of train operation where only one track is available for one direction. Faster and more frequent service can be provided and the average distance between stops can be raised three-fold. In order to

Figure 2. Acceleration curves, 10-car trains, 67 tons per car, level tangent track

take full advantage of the increase in length of average run, a high maximum safe speed is desirable to obtain a higher schedule speed.

Calculations have been made for multiple-unit train operation on a 1.3 mile run with various accelerating rates and maximum safe speeds. For a given increase in horsepower the improvement from higher accelerating rates is approximately the same as that for higher maximum safe speeds. As the power consumption is less when obtained through higher accelerating rates, this is the more economical method. The main point brought out by these calculations is the relatively small improvement possible in schedule speeds on short runs, even with large increases in horsepower capacity. By increasing the accelerating rate from 1.0 to 1.5 mphps and the maximum safe speed from 70 to 90 mph, the schedule speed is raised only 6.6 per cent. To effect this improvement requires 67 per cent more horsepower and 14.3 per cent more energy consumption. By raising the accelerating rate from 1.0 to 1.5 mphps and maintaining the 70 mph safe speed, a better schedule of only 3.3 per cent results with a 4.7 per cent increase in power consumption. Due to the larger capacity equipment, an increase in maintenance expense can also be expected.

It is doubtful if the results justify the additional expense, considering the very small improvement obtainable in short runs. When trains operate continuously with a uniform consist on uniform headways, decreased running time generally enables a reduction to be made in the total number of cars. However, in suburban service, where the rush-hour peaks occur twice daily for periods of approximately two hours and about 70 per cent of the cars are required only during these periods, the possible reduction in running time is far too small to permit more than one round trip to be obtained per car. Consequently, no reduction is possible in the total number.

Assuming that the average passenger ride is 30 minutes, the 3.3 per cent improvement in schedule speed referred to previously would mean a saving of only 59 seconds in the riding time. The operation of skip-stop service or express runs to or from a group of adjacent stations is far more advantageous than high accelerating rates and larger motor capacity.

Effect of Train Length

Another factor which must be considered in the application of new motive power is the maximum length of train to be handled. Due to the nature of the traffic, a railroad can determine quite accurately the number, destination, and arrival or departure times of its commuter patrons. With these data together with known track capacities, signal spacings, and platform lengths, it can determine the total number of cars and trains required to handle the traffic. Most large suburban operations now run 10- to 15-car trains during the rush-hours and 4-to-8-car trains during the base periods. Platform lengths frequently limit the number of cars per train, and for this reason, plus the fact that the operating cost per seat mile decreases as the seating capacity of the car increases, some roads use heavy cars with a 3-2 seating arrangement of 120-passenger capacity. Another road has designed and built double-deck cars with seats for 134 passengers. These cars are equipped with motors for multiple-unit operation, and have operating characteristics which permit their training with older cars in varying consists, and at the same time maintaining a constant accelerating rate and balancing speed to give identical service in both rush-hour and base periods of traffic. This is one of the decided advantages of electric multiple-unit car operation over steam, Diesel-electric, or electric locomotive-hauled trains. Even if it were permissible to operate any form of motive power in the New York region, it is very doubtful if steam or Diesel-electric power could economically handle the traffic without large-scale expenditures for additional main tracks to handle the increased number of shorter trains required to meet the present schedules.

Operating Flexibility

Maximum flexibility is another consideration which, to a large extent, governs the expenditure required for motive power and rolling stock. Undoubtedly, a minimum of terminal switching is desirable, but to obtain it is expensive. Serious study, therefore, must be given to justify any additional expense incurred in obtaining flexibility. With electric multiple-unit cars, three methods of operation are possible: all motor cars; semipermanently-connected 2-car units consisting of one motor car and one trailer; and motor car and trailer operation in varying consists limited to a minimum fixed ratio of motor cars and trailers. Obviously, all motor car operation gives maximum flexibility and the greatest protection of equipment and schedules in case of failure on one car in a train. However, these advantages are offset somewhat because of the large initial investment in motive power, and the high fixed charges due to poor utilization. Semipermanently connected 2-car units give almost the same high degree of flexibility, but with less protection of equipment and schedules with lower costs. Motor car and trailer operation gives the least amount of flexibility. It increases terminal switching costs and provides a minimum of protection, but substantially lowers operating costs. All of these operating methods are in use successfully on large suburban properties throughout the world. All have their advantages dictated largely by the conditions peculiar to each individual railroad.

Most postwar purchasing of new equipment has been for all motor car operation. Some of this equipment was for replacement purposes on roads where this type of operation had been in use for many years. The remainder was purchased to carry the increased commuter traffic, and any of the three methods of operation could have been used by keeping the new equipment in a separate pool.

Today, the railroads are striving more and more to reduce the cost of operation in spite of inflated labor and equipment costs. Increased revenue is essential, but usually considerable time elapses before a requested increase in rates is granted. Hence, the belief is prevalent that the maximum flexibility obtained with a consequent reduction in terminal facilities and costs justifies the additional investment required for all motor car operation.

Moreover, fixed charges and operating expenses can be lowered by maximum utilization of the new equipment in both base and peak service, and augmenting the latter with existing cars.

Another reason for all motor car operation is the public demand for faster and more deluxe commuter service in keeping with the latest trends in through service. As a result, new lightweight, semistreamlined commuter cars equipped with air conditioning, automatic heating and ventilating controls, fluorescent lighting, better seating, and washroom facilities have increased tremendously in cost over the pre-war equipment. The additional cost of traction motors and controls is now a much smaller percentage of the total cost of the complete car.

Effect of Existing Power Systems

It has been shown that electric multiple-unit operation of suburban service is the most advantageous from every operating standpoint including economy, provided the volume of traffic warrants the high initial cost of a complete electrification. The application of new equipment on an existing electrified railroad is influenced to a considerable extent by the voltage and power system, whether alternating or direct current. This is particularly true in regard to the number of motors per car and to the method of train operation, whether all motor cars or trailer operation. Since no new suburban electrification projects are planned in this country, all activity in this field will be limited to existing systems for many years. Therefore, it is well to consider how the type and voltage of the power system influences the selection of multiple-unit equipment.

Low Voltage D-C Systems

All suburban electrifications can be grouped into three general systems: namely, low voltage direct current at 600-650 volts; high voltage direct current at 1,500 or 3,000 volts; and high voltage alternating current at 11,000 volts. Two Class I eastern roads use the low voltage d-c system and operated 52,000,000 passenger car miles in 1946 with multiple-unit trains.

From the standpoint of motor car equipments only, the 600 volt d-c system offers the minimum in weight and cost. The motors can be constructed with a very low weight, the control is quite simple, and the switches are small since no high voltages are encountered. A modern 2-motor equipment of this type weighs 13,300 pounds—9,300 pounds for the motors and 4,000 pounds for the control equipment.

Two 600 volt d-c axle-hung motors per car, mounted on one truck, are in general use. Series parallel operation is used with fixed rate, automatic control equipment providing smooth accelerations with rates up to 1.5 mphps. This accelerating rate should not be exceeded as adhesion values above 20 per cent do not give adequate protection against wheel slipping in service when frequent starts are required under bad track conditions.

It is also possible to use on each car four 300-volt series-wound self-ventilated spring-borne motors with single reduction drive, field control, eand insulated for operation two in series and two groups in parallel on 600 volts. With 4-motor equipment and all axles motorized, full advantage can be taken of the total car weight for higher accelerating rates with only a nominal factor of adhesion. Recently, this type of equipment has been applied in subway service at a 2.5 mphps accelerating rate. On short runs and excellent track conditions, this feature is desirable to maintain high schedule speeds. Dynamic braking with a 4-motor equipment can provide a higher practical brak ing rate with a consequent increase in schedule speed. Subway and rapid tranist service with average runs of a half mile in local service differs greatly from suburban service where the trend is toward increased distance between stops. The increased first cost and maintenance expense of the 4-motor equipment, therefore, is difficult to justify in long-run high-speed service. A 4-motor 600-volt d-c equipment weighs 14,200 pounds—10,800 pounds for motors including gear units and 3,400 pounds for the control apparatus which includes a motor-generator set.

High Voltage D-C Systems

Two Class I roads use the high voltage d-c system, one at 1,500 volts and the other at 3,000 volts. Together these roads operated almost 21,000,000 passenger car miles in electric multiple-unit service in 1946. The use of 1,500 volts makes desirable, although not necessary, cars with four motors, thus permitting two 750-volt motors to be permanently connected in series with two groups in parallel. This arrangement gives two running notches with no resistance in the circuit, thereby reducing power consumption by the elimination of the resistance loss which would occur in the half-speed operation of a 2-motor equipment. To make the 4-motor equipment economical, trailer operation is essential using a semi-permanently coupled motor car and trailer unit. This type of operation not only gives good performance at a lower power cost than with all motor car trains of 2-motor equipments, but also reduces the first cost by eliminating the need for control equipment on the trailer car. A 4-motor equipment weighs approximately 30,000 pounds—20,000 pounds for the motors and 10,000 pounds for the control equipment. However, no electric equipment for traction purposes is required on the semipermanently coupled trailer, thus, the total electric equipment weight for the 2-car unit compares favorably with that required for two 600-volt d-c cars each equipped with two motors and control apparatus.

A 3,000-volt system requires four motors per car with the two 1,500-volt motors connected permanently in series. This likewise results in a 2-car (motor car-trailer) operating unit for economical reasons. This equipment is heavier and more costly than those for the 1,500- or 600-volt d-c systems, the electric equipment alone weighing approximately 41,000 pounds. The control equipment must be large and heavy to handle the high voltage. Inductive shunts, weighing about 3,000 pounds are required, and some sort of rotating apparatus is necessary to furnish the proper low-voltage control circuit power. Both railroads with 1,500- and 3,000-volt d-c systems operate multiple-unit trains at a 1.5 mphps accelerating rate and 70 mph maximum safe speed.

High Voltage A-C Systems

Three Class I roads use the a-c 11,000-volt system, recording 36,000,000 passenger car miles in multiple-unit service in 1946. Two roads use 2-motor equipments in all motor car operation, while the third uses 4-motor equipments with trailer operation, because part of its suburban service must be run on a 600-volt d-c third-rail system. This necessitated both a-c and d-c control equipment. It was believed at the time of installation that the additional expense involved in the large amount of control apparatus could be reduced by equipping only one of every three cars as a motor car. A-c equipments are heavier and more expensive than those for 600- or 1,500-volt d-c systems, but weigh less and are about equal in cost to the 3,000-volt d-c system. A recent 2-motor equipment weighed 26,600 pounds—11,500 pounds for the motors and 15,100 pounds for the control apparatus. A-c motor weights compare

favorably with 650-volt d-c motor weights, the former being about 15 per cent greater on a pounds-per-continuous-horsepower basis. However, a-c control equipment weights are much greater than those for the 600-volt d-c cars because of the heavy transformer required which, in turn, necessitates heavier car floor and center sill construction.

Noncommuter traffic in 1946 was down 35 per cent from 1944, but commuter business was up 11 per cent for the same period. The potential volume of this traffic should increase as residential areas develop at greater distances from the central business districts. By providing adequate automobile parking facilities at suburban stations, faster schedules, and more frequent service with high-speed modern electric multiple-unit equipment, the railroads in the high volume commuter business can expect a large share of this increased traffic without proportionate increases in operating expenses.

No Discussion

Large Indoor Power Air-Blast Circuit Breakers

G. E. JANSSON
NONMEMBER AIEE

Synopsis: This paper deals with some of the electrical and mechanical engineering problems encountered in developing large power air-blast circuit breakers. The characteristics and adaptability of the axial blast and cross-blast types of circuit breakers, and the reason for utilizing part of the latter principle for the design of large, indoor, medium voltage power circuit breakers will be discussed. A brief review of circuit interrupting phenomena, resistor application, air flow conditions, as well as general dimensions and outline, will be given. Finally, analysis and test data will be submitted indicating the possibility of further development of the high power cross-axial blast circuit breaker. That is a circuit breaker in which the contacts part at right angles to the blast, while the arc is immediately attenuated in the axial direction of the blast so that interruption occurs as in an axial-blast circuit breaker.

Axial Blast Versus Cross Blast

IN the early experiments with the axial blast circuit breaker, we came to the conclusion that the European design of these types of circuit breakers could, by proper modification of the interrupting element, be made to satisfactorily interrupt very large blocks of power.

We did not share the feeling of some contemporary investigators that an upper ceiling existed for the energy that could be interrupted by the nozzle type of interrupting element. As early as 1942, P. L. Taylor and H. W. Martin, after exhaustive tests, stated in an AIEE paper,[1] as follows:

"The evidence indicates that no such fixed ceiling or point of breakdown of relative values exists, and that still further development and extension of the potentialities of the device may be expected."

This statement has received further confirmation both by our own tests, and the successful operation of circuit breakers in service, as well as by tests carried out by European designers.

We therefore wanted to retain the axial blast principle for interruption, but for reasons enumerated later, desired to adopt certain structural features of the cross blast design, such as greater ease of design for large ampere carrying capacity by the use of conventional multiple bar and finger type contacts, making the cross-blast circuit breaker more adaptable to the high power requirements of this class of circuit breaker.

The combination of interrupting and isolating contacts in one moving member gives greater ease and freedom in the design of the sequence co-ordinating mechanism for the necessarily heavy current carrying members required.

The cross-blast structure appears somewhat easier to adapt to conventional switchgear and cell mounting. Another factor is the easy inspection of contacts, particularly as the blade or moving contact can be visually inspected when the circuit breaker is in the open position. The inspection of this contact will give a general idea of the condition of the finger contacts as well.

A close study of arc transfer during interruption in an air-blast circuit breaker shows that the arc starts at right angles to the blast and then is elongated in the axial direction of the air stream when final interruption occurs (Figure 1).

It is well recognized that the main structural advantage of the axial-blast circuit breaker over the cross blast is its easier adaptability to high-voltage insulation, particularly for outdoor applications. This is because the interrupting chambers can be fully enclosed in porcelain tubes. The axial-blast type of circuit breaker thus is ideal for high and supervoltage applications and for installation outdoors where excessive dust or corrosive fumes are encountered. In this class of circuit breakers the carrying current ability required does not exceed values which can be carried readily on butt type of contacts.

In the indoor, high power medium voltage class of circuit breakers carrying currents of 2,000–4,000 amperes are common, requiring special multifinger contacts in order to keep the temperature low enough to prevent damaging oxidation.

Review of Interrupting Devices

In looking through the technical literature for the last 10 to 15 years, it is surprising to find so many different versions of designs, all of which evidently have been brought to satisfactory performance. It, therefore, appears that the particular arrangement used is not of prime importance, but rather that the proper dimensioning and configuration of the device chosen, within reasonable limits, are the deciding factors. In a recent survey, the writer collected 25 different designs, all of which are in service, and most of them sufficiently different so that one would expect considerable variation in interrupting performance.

Figure 1. Comparison of axial and cross-blast circuit breaker arcs

Paper 48-305, recommended by the AIEE switchgear committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted August 2, 1948; made available for printing September 15, 1948.

G. E. Jansson is with the Allis-Chalmers Manufacturing Company, Boston, Mass.

In attempting to evaluate the action of a stream of air surrounding an arc axially with the flow direction with that of an arc held perpendicular with the flow leads us to the following deductions.

Assuming that thermal energy ions are diffused radially from the arc. Then as shown in Figure 2, the force acting on these particles in the axial blast would be

$$F=\sqrt{f^2+d^2}$$

when

f = air flow force and d = the diffusion force.

At a distance x from the axis, this force would be uniformly acting on $2\pi x p$ particles. Now in an arc held perpendicular to the flow, the positive and negative components cancel out and the remaining radial vectors would vary from 0 to d as shown according to the formula $d \cos \alpha$ and the force at any point x is

$$F=\sqrt{f^2+(d \cos \alpha)^2}$$

This force again acting on $2\pi x p$ particles. However, since $d \cos \alpha$ varies from $d=d$ to 0, it is seen that the resultant force is considerably smaller than for the case of the arc parallel to the stream of air. Physically, the difference may be somewhat smaller than indicated by the above figures due to other factors influencing the result.

For this reason, some five different types of arcing structures were made up, and preliminary tests were run to obtain some basic data for the final interrupting chamber designs. Two of these designs developed insulation weaknesses which led to failures at relatively low currents. One device failed on the fifth CO (close-open) shot at about 19,000 amperes and 11,000 volts, single phase. This device had previously interrupted 12 CO shots at varying currents from 500 to 11,500 amperes at 13,000 volts across the single-phase break.

One interrupting device interrupted 20 single-phase CO shots at from 500 amperes to 38,200 amperes without failure. Another device of the cross-axial blast design interrupted 25 single-phase CO shots at currents of from 500 to 55,000 amperes, as shown in Table I, all without failure, or arcing times indicating serious stress.

Without change in contours or dimensions, the indications on these two devices were that the limit in interrupting current had not been approached as far as it had been possible to carry out the test in the time allotted.

A careful analysis and study of the test records, however, indicated that still further improvement in performance and increase in interrupting capacity may be obtained by slight modification of dimensions and contours of the device finally adopted for production. The preliminary tests confirmed the interesting facts that with the correspondingly proper dimensioning and configuration, practically the same interrupting performance could be obtained with devices of widely different design.

Figure 2. Thermal convection and air-blast forces on arc particles

Air Flow Characteristics

During these test series considerable difference in air flow characteristics was observed from that of the axial-blast circuit breakers. The reason for this difference apparently is the open to atmosphere construction of the cross-blast device, in contrast to the practically closed nozzle of the axial blast design. In the former, the flow and pressure follows somewhat that of a Laval nozzle. In the latter, an oscillatory pressure wave results.

Figure 3A illustrates the approximate air flow and pressure conditions of an axial or nozzle-type of circuit breaker, and Figure 3B shows that of the cross-blast design. These diagrams indicate readily that in the axial blast with the initially closed nozzle arrangement, the air pressure will momentarily rise to a certain value, and then oscillate down to a steady condition in which a relatively slow uniform decrease of pressure with time occurs. The maximum magnitude of the momentary pressure peak may considerably exceed the tank pressure, depending on length and volume of feed line between main blast valve and nozzle, as well as amount of air leakage around the nozzle contact itself.

In other words, when the air blast reaches the nozzle, a pressure wave is reflected from the nozzle towards the tank in the same way as an electric potential wave is reflected from the open end of a long transmission line. This reflected pressure wave is superimposed on the tank pressure.

So far we have discussed the air flow and pressure in an axial-blast circuit breaker at no load. Now, what happens to this pressure and flow when an arc is interrupted? Since the arc is at a very high temperature, that is in a state of excessive thermal energy, it follows that the arc must be surrounded by a high pressure zone. Now, if the current is increased to a sufficient value, depending on the diameter of the nozzle so that this high pressure zone, which may considerably exceed the tank pressure, completely fills the nozzle it is clear that the air flow will be stopped and a pressure rise as described previously would occur. As a matter of fact, at a sufficiently high current the flow of air is not only stopped at the nozzle but may actually reverse, flowing towards the tank. This usually leads to failure as the time lag for rectifying this reversed pressure wave usually exceeds the time interval of zero current.

In the cross-blast type of circuit breaker the air flow passage in the conventional designs are relatively open to atmosphere, and the no-load air flow conditions, therefore, more or less assume the characteristics of the flow in a Venturi tube or DeLaval nozzle.

This means that nodes or points of varying pressure and flow velocities are created. When, however, a high power

Figure 3A (left). Axial-blast circuit breaker air flow

Figure 3B. Cross-blast circuit breaker air flow

Figure 4. Current and voltage without parallel resistance to arc

arc is drawn a stoppage of air, or even a reversal, as described before for the axial-blast circuit breaker may take place. The energy value at which this occurs depends on the dimensions and configurations of the air passage. In the cross-blast circuit breaker this air flow stoppage and accompanying pressure rise can occur only after the contacts have been separated and the arc drawn for some time.

One of the troubles we encountered in some of our first experimental arc interrupting structures was a too open front exhaust along the moving blade which required correction before successful operation could be obtained.

A review of available literature on flow of compressible fluids indicated a rather mathematically complex solution, and then only of some rather specific and limited construction such as the Venturi or Laval nozzle, and so forth.

Some idea of the effect of harmful eddies and contractions can be obtained from pictures of flow of noncompressible fluids, such as water with aluminum powder for visibility. However, these are not directly applicable to compressible liquids, and are at most only a rough guide. Pressure and air velocity measurements are the only sure way to obtain reasonably accurate data on a particular structure.

An approximate ratio of effective nozzle area to main blast valve area of 1 to 3, or 4 appears required to obtain approximately full tank pressure on the momentary pressure peak.

Blast Valve

The component of the circuit breaker that controls the air flow is the main blast valve. The design of this important item is a major problem in itself. Several specific requirements have to be fulfilled to give maximum efficiency and serviceability. For instance, it must be fast acting, it must have a minimum pressure drop across it, and a minimum energy loss due to eddies. Its main parts must be readily accessible for inspection and exchange. It must be sufficiently rugged to withstand thousands of operations without servicing or renewals.

In our early designs of air-blast circuit breakers we followed the European design of pressure operated valves. This gave a very rugged valve with excellent air flow characteristics. In larger sizes, however, it became heavy and awkward. Because of this, inspection and change of valve seats became a consumer of time and manpower. This design was therefore superseded with a differential valve.

At the present time, however, further development of the direct pressure operated blast valve has been carried out to a point where the same easy access for inspection and servicing can be obtained. Due to its inherently faster operating time it may eventually supersede the differential type of valve.

The reason for the longer mechanical opening time required by the differential type of valve is the large dead air space under the valve which must be evacuated before action takes place. For instance, computation shows that the time in cycles to equalize the pressure under the piston of a 4-inch diameter differential valve with as small a dead air space as practicable would require 1.63 cycles, whereas the time to build up sufficient air pressure to begin movement of a pressure piston operated valve is of the order of 0.402 cycles. In both times figured a 1/2-inch diameter pilot valve was considered. The opening time of this pilot valve is not included.

As mentioned before, an advantage of the cross-blast circuit breaker is the inherent fixed mechanical sequence between circuit interruption and isolation. An equally important and easily obtained fixed mechanical or pneumatic relation may be had between contact separation and main blast valve opening. Approximately 3 cycles or less time from energizing trip to contact separation with an average arcing time not exceeding 1/2 to 1.0 cycles can be obtained readily.

Contacts

Contact arrangement for the cross-blast circuit breaker follows along the conventional blade and finger design. However since in the cross-blast circuit breaker the same contacts are used for both opening and closing operations, a rather different and severe problem of momentary current transfer without undue preheating and contact burning is introduced. Mechanical chattering, as well as magnetic blowoff of the contacts at high current values must be fully counteracted to prevent serious contact errosion and possible failure.

Through a careful analysis of a large number of contact making tests, we were able to reasonably well define the contact form, spring placements and pressure which eliminated the chattering and burning even on high current shots.

Parallel Resistance

The probable current and potential phenomena occurring during interruption of an arc in a circuit containing inductance and capacity is shown in Figure 4. In this it is assumed that due to the ever-increasing gap distance with its extension of arc length, cooling and scavenging action of the blast, and so forth, the current tends to decrease at a faster rate than given by $Zi = I\sin\omega t$.

The difference between the actual current and the current given by the foregoing figure is in the form of an oscillating charging current Zi_c which oscillates with a frequency of $f = 1/2\pi\sqrt{LC}$. The damping out of the oscillations is dependent on the circuit and arc resistance. The arc voltage, that is voltage across the circuit breaker gap, increases with the decrease of the instantaneous value of the current and finally reaches the extinction value e_{ax}. Instantly, the system voltage attempts to establish across the contact gap, but due to the oscillating charging current mentioned before an oscillating voltage wave is produced which, super-

Figure 5. Current and voltage with parallel resistance to arc

imposed on the system voltage, gives rise to a voltage peak E, as shown.

It is now evident that if permanent interruption of the circuit is to be accomplished, the rate of dielectric recovery, measured in gap voltage to break the gap deg/dt must be greater than the rate of voltage rise der/dt or mathematically expressed $deg/dt > der/dt$. Further, anything done to reduce the rate der/dt is enhancing the interrupting ability. This can be done by introducing a resistor in series with the arc of such magnitude that the oscillatory capacity current becomes aperiodic. This is obtained when the value of this series resistance $R \geqq 2\sqrt{L/C}$. With a resistor of this magnitude the interruption may take place as shown in Figure 5. In this arrangement the resistor is initially in parallel with part of the arc path. Now as the current decreases the arc voltage will increase and, the current flowing through the parallel resistor will increase proportionally to the increase in arc voltage. Finally so much of the current flows through the resistor that the parallel arc becomes unstable and is extinguished. The resistor is now in series with the remaining arc. Since this resistor is many times greater than the short circuit impedance, di/dt will decrease and the steepness of the recovery voltage will be independent of the circuit constants, hence a slowup of der/dt to a value less than that at which interruption may take place.

In Figure 5, the slope of the gap voltage has been exaggerated for illustration, but it is evident that by introduction of the resistor, not only the steepness of the gap voltage but also the actual magnitude has been considerably reduced.

Some recent investigations are tending to show that below a value of der/dt — 300–400 volts microsecond the air-blast circuit breaker is independent of the rate

Figure 6. Outline of type AB-15 air-blast circuit breakers

of recovery voltage rise, but above this figure interrupting ability rapidly decreases with the increase in recovery rate. This seems logical since for a certain pressure and structure configuration the rate of dielectric recovery may have a natural time constant, that is, a more or less fixed rate of dielectric recovery. It is then evident that any circuit voltage rise below this value will have no effect on interrupting ability. As this fixed value of dielectric recovery is approached, considerable reduction of interrupting energy may be required in order to retain the requirement for interruption mentioned previously. It is hence clear that improved interrupting ability will result as long as the resistance in series with the arc is low enough to effectively reduce the rate of arc re-establishing voltage.

Figure 6 shows the experimental circuit breaker and tabulation of dimensions.

Tests

Table I is a summary of preliminary tests on the interrupting device finally adopted for development as the most satisfactory from performance, maintenance, and economic considerations:

All tests were carried out at 150 pounds per square inch tank pressure in order to compare all devices at the same pressure level, and the tests were single phase, and except as marked, with a 12-ohm resistor. Figures 7 and 8 show typical oscillograms obtained during these tests.

Conclusion

We have briefly surveyed the major and fundamental engineering problems

Figure 7. Oscillogram of single-phase close-open interruption of 15,800 amperes

Figure 8. Oscillogram of single-phase close-open interruption of 55,000 amperes

in the development and design of high power air-blast circuit breakers. We have endeavored to at least indicate possible ways of solution and to give a better understanding of the factors affecting air-blast circuit breaker performance.

It is true that we have not yet reached ideal solutions for a good many of the problems encountered, and large scale research on all major phases is still being vigorously pursued with this as a goal. This specialized research, backed by long experience of American circuit breaker manufacturers in building oil and air circuit breakers, which successfully handle the greatest power concentrations in the world, will insure an improvement in circuit breaker performance, both technically and economically, to the mutual benefit of both users and manufacturers.

Discussion

Robert H. Nau (University of Illinois, Urbana, Ill.): I am particularly interested in this paper which describes another version of a high-power compressed-air circuit breaker. My interest is enhanced more when I observe that the circuit breaker still stands, after considerable laboratory testing, very much as it existed on paper in 1946 when I was collaborating as design and development engineer for Allis-Chalmers Manufacturing Company with Jansson.

The hook-contact, which is actuated by a high-speed pneumatic operator, the direct-flow pipe from the air tank to the arcing region, and the single air tank, which provides a foundation for the circuit breaker proper, have proved again to be a very desirable arrangement for a high-power, indoor, cubicle-enclosed, air circuit breaker.

However, the test data which have been presented do not warrant rating the circuit breaker for more than 500,000 kva. It appears that the tests were limited by the maximum short-circuit capacity of the Allis-Chalmers High-Power Testing Laboratory. In which case, it has then been demonstrated that the circuit breaker is ample for the 500,000 kva interrupting capacity, but not necessarily for more. The fact that the circuit breaker has successfully opened approximately 55,000 amperes rms at the low voltage of 1,100 volts, and that other axial-blast circuit breakers have lent themselves well to high-voltage insulation in the form of outdoor circuit breakers does not provide any basis for extrapolating the kilovolt-ampere rating to correspond to full recovery voltage on a single-pole unit following an interruption of 55,000 amperes rms. My analysis of the present data, of other test data on both axial-blast and cross-blast circuit breakers, and of the air-flow and arc relationships in air-blast circuit breakers does not suggest very strongly that the axial-blast interrupter can be adapted to the pneumatic circuit breaker proper, with any amount of adroit dimensioning and contouring, for an interrupting capacity of 1,500,000 kva.

B. P. Baker (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The author appears to be in the midst of making the very important decision—to determine what kind of a compressed air circuit breaker he is going to develop for heavy-duty indoor powerhouse service. It is gratifying and reassuring to know that a man with Jansson's broad experience and personal contact with European practice for a number of years, is now confirming the decision we made ten years ago. It is sincerely hoped that the next years will not prove that we were both in error.

I agree entirely with Jansson's conclusions regarding the general circuit breaker construction, type of contacts, type of interrupter, and operating pressure of 150 pounds per square inch. During the last nine years, we have delivered over 600 circuit breakers built along these lines, 40 per cent of which have been for 1,500,000 and 2,500,000 kva service. These circuit breakers have given an excellent account of themselves. Two illustrations are shown in the publications later referred to,[1,2] giving the general construction of these circuit breakers. The reservoir, mechanism, and associated mechanical parts are located in the lower compartment; the contacts, interrupter, and all live parts are located above. This arrangement has worked out quite well to give a straight simple air flow from the reservoir through the blast valves, interrupters, coolers, and into the gas receiving chamber at the top. These features together with a properly designed interrupter have made the interruption of 2,500,000 kva possible with air at 120 to 150 pounds per square inch, without the use of a shunting resistance. The contacts are of the finger and bayonet type, and as Jansson points out, the moving contact is completely withdrawn from the interrupter when the circuit breaker is in the open position. All contacts are, therefore, accessible for inspection and have been found adequate for continuous current carrying capacity up to 5,000 amperes. Previous publications[1,2] describe the circuit breaker and give interrupting test data up to 105,000 amperes rms at 13.2 kv, 2,000 volts per microsecond at 125 pounds per square inch without the use of a resistance shunt. It seems unfortunate that the author should delete these references from his references, especially after having followed their teachings in such great detail.

According to the teachings of the articles shown in my references referred to above, the circuit breaker ratings shown in Jansson's Figure 6 should be possible; and established American practice agrees with the dimensions shown. However, direct extrapolation from the author's best data—55,000 amperes at 1,100 volts, Figure 8, to the ratings and dimensions shown in Figure 6, seems entirely out of the range of engineering estimating.

I believe I was one of Jansson's contemporary investigators, whose opinion he did not share, "that an upper ceiling existed for the energy that could be interrupted by the nozzle type of interrupting element." While I admit that this statement should have been more quantitative, I still feel that for a given voltage rate of rise of restored voltage and air pressure, the unshunted nozzle has a lower current ceiling than a splitter type of interrupter.

However, as the rate of rise of voltage is decreased and the air pressure increased, the current ceiling is raised. This process continues on down below the 300 volts per microsecond referred to, even down to where the restored voltage is comparable to the sinusoidal 60-cycle wave. This theory, if carried too far may lead to impractical shunts which would place too much burden on the break interrupting the residual current. We have by use of shunting resistors, interrupted 65,000 amperes at 22 kv and 40,000 amperes at 44 kv on a single nozzle at 220 pounds per square inch; the residual current being interrupted by a second nozzle. At lower voltage, 15 kv and high values of current, this solution appears less practical than the one using the splitters and cross-blast which Jansson seems to have selected.

Flashovers of Suspension Insulators Due to Contamination

H. A. ADLER

FELLOW AIEE

Synopsis: Flashover of suspension insulators on steel tower lines, traceable to an accumulation of dirt followed by a deposit of moisture, has been the source of numerous outages of high-voltage transmission lines. The aim of the investigation described in this paper was to determine means of increasing the insulation level of existing lines under fog and dirt conditions. Methods were developed to simulate, in the laboratory, the conditions of dirt and fog which cause flashover of insulators in the field. Using these methods, a study was made of the phenomena of flashover of contaminated suspension insulators. The benefits to be derived from lengthened strings and the superiority of special fog-type units with increased leakage distance were determined. Other means of reducing the hazard from dirt accumulation are suggested.

Operating Experience

IN the Chicago area on the system with which the authors are associated, the source of contamination of insulators is industrial dirt. The seasons in which flashover troubles are most likely to be encountered are late winter and early spring. During the winter, the insulators receive little, if any, benefit from rain washing so that dirt accumulates. Following this exposure is the season when fog conditions most frequently prevail and flashover is most likely to occur. Operating experience has, in general, followed this pattern. A series of insulator flashovers occurred in 1944 and 1945 at several locations, on 132-kv and 220-kv overhead lines in the Chicago area. These troubles had the following characteristics in common:

1. They occurred in locations where insulators were exposed to contamination such as industrial dirt, fly ash, and railroad smoke.

2. They occurred usually after prolonged dry periods during which the contaminants could accumulate on insulators. However, there were cases when insulator troubles occurred after a very short time of exposure to contamination.

3. Flashovers occurred always during periods of fog or light drizzle which made the deposits on the insulators conductive.

The contaminants usually can be removed by washing of the insulators. However, this procedure is expensive so that frequent washing is undesirable. A continuous testing program is necessary to determine the need of washing.

Aim of Investigation

After a study of all information available from service experience and an extensive survey of the large amount of published information on this subject, the investigation was directed towards reinforcing the insulation strength of the suspension strings, under conditions of contamination, to such an extent that the insulators could withstand prolonged periods of contamination without trouble. It was expected that with added insulation strength, it would be possible to establish a cleaning schedule, similar to the overhauling schedule for other equipment, providing for washing of insulators only once a year. Such a procedure would not only reduce the frequency of washing, but also the washing could be scheduled at a convenient time, and under favorable weather conditions, thereby further reducing maintenance expenses. Under the conditions encountered in the Chicago area it is not considered practical, from an engineering and economic standpoint, to attempt complete elimination of insulator washing.

Test Methods

In order to compare the effectiveness of various methods of reinforcing the insulation strength of suspension strings under conditions of contamination, it was necessary to develop a method of artificial contamination and fogging. Studies in the field would have required an undue amount of time and would have been complicated by the many uncontrollable variables.

A new procedure of artificial contamination was developed which fulfilled the following three basic requirements.

1. Contamination producible in the laboratory in a short time.

2. Results closely reproducible.

3. Reasonable duplication of service contamination in type and pattern, and in its electrical effects.

Briefly, the method consists in depositing on each insulator a mixture of 75 per cent, by weight, of fly ash and 25 per cent Portland cement under a carefully controlled procedure of alternate fogging by means of steam and dusting through specially designed nozzles to produce a pattern of contamination similar to service conditions.

A weighed amount of the fly ash and cement mixture sufficient to produce the desired contamination was placed in a dust gun operated by controlled air pressure. Dust from this gun was blown against the insulator surfaces through two nozzles, one directed vertically upward against the lower surface of the insulator and the other directed horizontally against the edge. During the

Paper 48-307, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted July 30, 1948; made available for printing September 9, 1948.

H. A. ADLER and W. H. WICKHAM are senior engineers with the Commonwealth Edison Company, Chicago, Ill., and M. S. OLDACRE is director of research, Utilities Research Commission, Chicago, Ill.

The authors wish to acknowledge the work of E. Schmitt, F. T. Carver and R. F. Freeman in conducting the large number of tests required for this investigation.

The apparatus for producing the fog was designed and developed by R. Patzelt and F. T. Carver.

Figure 1. Equipment for contamination and fogging of insulators

process of contamination the insulator was slowly rotated on its vertical axis and was energized at 10 kv. This voltage is of the same order of magnitude as the average potential drop across a unit in service. Alternate fogging and dusting for measured time intervals, first with the vertical nozzle in positions to contaminate the lower surface, then with both nozzles, produced the desired pattern and degree of contamination. The dust was deposited most heavily in the bottom of the grooves on the under side, and fairly uniformly over the top surface. This closely approximates the manner in which dirt has been observed to collect on insulators in service.

Fog conditions were reproduced by directing a stream of wet water vapor, supplied by low-pressure steam, against the insulators. The apparatus for fogging and contaminating is shown diagramatically in Figure 1.

By carefully controlling the methods of contamination, fogging, and flashover, results obtained in flashover voltage tests were reproducible within ±10 per cent in short strings and even closer in long strings. Surface resistances showed wider variations. This would be expected from theoretical considerations because a narrow ring of relatively clean or dry area around the surface of a dirty fog-wet insulator will increase the surface resistance markedly without appreciably affecting the flashover voltage. For this reason it is felt that flashover voltage is a better criterion of the degree of contamination than is the surface resistance. The degree of contamination was so selected that the fog flashover of the insulator was approximately 1.5 times the average potential drop across a unit in service. This amount of contamination was found by field experience to be dangerous.

It should be noted that in making flashover tests on fog-wet contaminated insulators it is essential to have a power source of adequate capacity. Flashover of insulators under such conditions is preceded by arcing over parts of the surface and momentary increases in current. The regulation of the source must be such that the voltage will be sustained during these current changes, otherwise the results will be erratic. Furthermore, with the application of voltage to the wet and dirty insulators some drying takes place. The voltage must be increased rapidly to flashover in order to minimize the effect of drying.

Increasing the Length of Suspension Strings

First, a study was made of the advantages to be gained by increasing the length of suspension strings. The opinions expressed with regard to the value of such a scheme were found to be contradictory. The opinion of those who believed that adding of extra insulators was of no value under dirt and fog conditions, is based on the fact that the moist dirt on account of its high conductivity upsets the potential distribution along the string. In general, it must be expected that contamination may be nonuniform along the string. Then a relatively clean insulator on account of the greater I^2R losses will dry faster than the dirtier insulators. The clean and dried insulator will then take all or most of the voltage drop and initiate a flashover. According to this argument there will be no advantage in increasing the length of a string as there will always be some relatively clean insulator which will start the flashover of the string.

It was therefore necessary to include in this investigation the study of mixed strings of clean and dirty insulators. The most important phases of this investigation are shown in Figures 2 to 7. Figure 2 shows the comparatively slight reduction in flashover voltage under fog conditions when the insulators are clean and the great reduction when they are dirty. Figure 3 demonstrates that with regard to flashover voltages the artificial contamination produces results comparable to field conditions. Table I shows that with regard to surface resistivities, artificial contamination produced results of the same order of magnitude as field conditions.

Table I

Number of Insulators in String	Surface Resistance (Moist) Megohms Field Dirtied	Artificially Dirtied
6	0.49–0.66	0.65–0.80
18	1.3	1.5

In the study of the effect of clean insulators in strings of dirty insulators, a series of determinations were made of the potential distribution along the string. The right side of Figure 4 shows the potential distribution is not changed by fog if the insulators are clean and not changed by contamination if the insulators are dry. There is no measurable voltage drop across dirty and moist insulators and all the voltage is carried by the clean insulators under fog conditions.

As the next step in the study of mixed strings, Figure 5 shows the fog flashover voltages of a string of four with one to four clean insulators in the string. It can be seen that the minimum value occurs not for four, but for three dirty

Figure 2. Flashover voltage of suspension insulators

Figure 3. Fog flashover voltages for field-contaminated and artificially-contaminated insulators

Figure 4. Potential distribution for four-unit string

insulators. This minimum value was about 11 per cent lower than the flashover voltage for a string with all dirty insulators. The figure shows two values in each case except for four insulators. The differences are caused by changes in the relative positions of the clean insulators in the string. The lower values were obtained in each case with the clean insulators on the line end.

In view of the observations on the effect of the location of clean insulators in the string upon the flashover voltages, studies were made on a string of six with one clean insulator in all possible positions, the other insulators being dirty. The results are shown in Figure 6. It is of special interest that the clean unit started to flash over at increasingly lower voltages the nearer it was to the line end. However, contrary to the opinion discussed before, the flashover of the clean unit did not result in the flashover of the complete string. This was the case because the flashover voltage of the five dirty units in the string was greater than that of the single clean unit. The flashover voltages for the mixed string were close to the flashover voltage of an all dirty string. The minimum value for the mixed string was six per cent below the flashover voltage for the all dirty string.

Finally, tests were made on strings of 18 with one, two, and three clean insulators on the line end, the remaining insulators being dirty. The minimum fog flashover voltage was obtained with three clean and 15 dirty insulators and was less than five per cent below the value for a string of 18 dirty insulators.

From these data it was concluded that the presence of clean insulators, especially in long strings, would not result in appreciably lower flashover voltages than for strings consisting of only dirty insulators. As a consequence it appeared justified to study the effect of adding insulators to a string using only dirty insulators without the time consuming study of mixed strings.

The lower curve of Figure 7 shows the results of fog-wet flashover tests on up to 24 dirty insulators. It can be seen that adding insulators does produce a definite increase in the fog-dirt flashover voltage although the rate of increase becomes somewhat less for longer strings.

On the Chicago 220-kv line the normal length of a suspension string is 18 units. An increase to 24 units produced an improvement of about 18 per cent in fog-dirt flashover voltage according to Figure 7. The maximum number of insulators which can be added to suspension strings on this line is eight. This can be done only on certain towers. It is estimated that addition of eight units will result in a 23 per cent improvement.

Fog Type Insulators With Increased Leakage Distance

Addition of eight units to suspension strings is not always possible on account of limitation with regard to clearances. For this reason studies were made on fog-type insulators designed for fog and dirt conditions on the Pacific coast. These insulators have nearly 50 per cent more leakage distance than the standard units. Figure 7 shows the superiority of these insulators over the standard insulators under fog-dirt conditions. On single circuit towers of the Chicago 220-kv line, 16 fog-type insulators can be installed with sufficient clearances. The data show that these 16 insulators give a much greater factor of safety than can be obtained with the 18 standard insulators normally installed or even with 24 standard insulators. No such advantage of fog-type insulators can be expected on dead end positions as in this case the large protective under surface of these insulators will be exposed to contamination. Therefore, such strings should be lengthened with standard units.

Reversing of Strings

At locations where the lower grooved surfaces of the dead end insulators face a source of contamination, the fog flashover of the insulators may be appreciably reduced. Since the larger portion of the leakage path is in this lower, grooved

Figure 5. Fog flashover voltages for mixed string of four insulators

Figure 6. Fog flashover voltages for mixed string of six insulators

Figure 7. Fog flashover voltages for artificially-contaminated standard-type and fog-type insulators

surface, reversal of the insulators should be expected to result in an improvement by protecting these surfaces from unidirectional contamination. Test results shown in Table II for artificially contaminated 6-unit strings indicate that a considerable improvement can be obtained under these conditions by reversing the insulators.

Silicone Coated Insulators

Since silicone films are known to be very effective in repelling moisture, a series of tests were made on standard insulators covered with silicone. The idea was that dust would adhere less readily to a surface on which no moisture film could form. This phase of the investigation has not been completed. From the results at hand it would seem that some advantage can be obtained from such a coating if it can be made durable enough to withstand long exposure to the elements.

Conclusions

1. Increasing the length of strings of standard suspension insulators increases the flashover voltage under dirt and fog conditions.

2. Fog-type insulators in suspension strings are superior to standard insulators under fog and dirt conditions.

3. Installing dead end insulators with the smooth side towards the principal source of contamination results in improved fog flashover characteristics.

4. These schemes were put into effect at critical locations on the Chicago 220-kv line in the winter of 1946–1947. It is expected that by these measures the interval between insulator washing on this line can be one year or more, and that the washing can be scheduled at a convenient time similar to the scheduling of overhaul of other equipment. The result should be a considerable saving in maintenance expense. No washing has been done during the $1^1/_2$ years since the changes were made. At one especially critical location where all strings of standard insulators were lengthened, hand cleaning was done once when the line was out of service for other reasons. This was an added precaution, and possibly not necessary. Several years of experience will be needed to determine the permissible interval between washings.

Discussion

P. L. Bellaschi (Consulting Engineer, Sharon, Penn.): Insulator contamination is a problem which confronts engineers in many lands. Although considerable progress has been made in recent years, the problems it presents have not been completely solved as yet. We are fortunate, therefore, in having the more recent findings as well as the general subject reviewed at this time.

In the course of an engineering trip throughout South America several years ago, this problem was brought to my attention repeatedly. Due to limited space, I shall confine myself here to a typical instance, with reference, specifically, to the difficulties encountered in the São Paulo region in 1944.

São Paulo lies inland some 50 miles from the sea on a plateau at about 2,000 feet (600 meters) elevation. The land rises abruptly from the seashore to the upper lands. Transmission lines (80 kv) from the hydroplants near sea level negotiate the bluff, then continue inland on the plateau to São Paulo. The lines are of steel tower construction and were insulated with four suspension insulators at the time. The operating voltage is 80 kv line-to-line (46 kv to ground). The dry flashover voltage being in the order of 250 kv, ratio between operating voltage and dry flashover is about 0.20.

Along the bluff, due to the warm humid air rising up to the plateau, the insulators are drenched year round and present no problem. On the plain, the rain comes at frequent intervals except for the dry season which lasts some three to four months—from May to August. During this period, the insulators of the lines on the plateau accumulate dust. The presence of new factories in the São Paulo region during the war further contributed in some measure to the contamination problem.

In 1944, the dry season had been unduly hot and the rains were fully a month overdue. Coupled with these conditions, this was the time (September–October) of heavy fogs. Starting in the evening, the fog would roll up the sea across the plateau and by early morning occasional flashovers would follow. For instance, on August 18, between 5:40 and 7:15 a.m., seven line outages were recorded. Under these conditions of combined dust, industrial contamination, and heavy fog, insulators that normally had a flashover strength of 250 kv would suffer a drastic reduction down to less than 20 per cent (46 kv, the operating voltage) with the result that copious flashovers would result at operating voltage. Under these adverse conditions, and in spite of some attempt at cleaning, there were a total of some 20 or more outages recorded in the course of a few weeks.

At the main hydrostation as well as at other generating stations, the neutral is solidly grounded but at the receiving stations (near São Paulo) neutrals are grounded through 100 ohms. The result of this was that when an insulator string would flashover, due to the overvoltages developed from the arcover propagated to the entire system, these overvoltages would induce flashover on other parts of the system because of a general lowering of the insulation throughout the system. For instance, at 6:40 a.m. on September 28, six of the lines tripped, at intervals possibly some 20 or 40 cycle and even more apart, according to the oscillographic records. During this period, a number of flashovers had occurred in the main receiving station.

In one instance, this station was de-energized in order to repair the damage. When all had been cleared and an attempt made to re-energize the bus, the insulation would not sustain the voltage. During the shutdown, the fog had completely wetted the insulation. Half an hour later, at 5:00 a.m., conditions apparently became more favorable and it was possible to return the station in service. Judging from the noise and pronounced sparking on the bus insulators, the leakage currents certainly must have been relatively high, gradually subsiding as the insulators dried out.

Under these circumstances, it was apparent that four suspension insulators resulted in a "tight situation." More liberal insulation was recommended. A cleaning and washing program of the insulators on the line and in the station was instituted.

First, I would like to ask the authors of the paper whether switching surges superimposed on the sustained 60-cycle operating voltage might not have precipitated some of the flashovers experienced on their system. If such should be the case, then a long sustained 60-cycle voltage with switching overvoltages superimposed thereon might well be a test of significance to give consideration in investigations of this character. In any event, it would seem that the 60-cycle test voltage should be sustained for a reasonably long period of time.

Second, have the authors observed either by cathode-ray oscillograph records or otherwise abrupt leakage current discharges preceding and possibly precipitating flashover?

And third, I would like to ask the authors whether in their view cleaning of the insulators under conditions of severe contamination as discussed here might not be predicated equally as much by radio-noise considerations in addition to the potential flashover hazard. Have radio-noise tests been conducted in the field and in the laboratory under these conditions?

The authors might find of pertinent interest the various contributions by W. Wanger presented in France in 1939 and later published in Switzerland.[1,2] Perhaps he was the first to investigate the relative effect of voltage duration on the flashover of contaminated insulators. Investigations conducted by the writer on insulators subjected to chilling in dry ice (CO_2) and then exposed to a humid atmosphere, and subjected, subsequently, to impulse, switching, and 60-cycle voltages confirm the work by Wanger generally well. The 60-cycle strength can well be reduced to 20 per cent of the dry strength, especially if the porcelain surface is contaminated. The impulse strength is not affected as much. The switching-surge strength is intermediate, the amount of the insulation strength is lowered depending on the duration. Dew and fog in combination with contamination in general present the worst condition.

In view of the increasing importance of the problem and the fact that we have not yet completely solved it, it would be well for the Transmission and Distribution Committee to continue giving its attention to this matter.

M. S. Oldacre: This paper, together with three others on the same subject[1,3,2] cover some of the many phases of the insulator contamination problem and it is hoped that they will aid in promoting further study of the subject.

The author's paper should be read along with a companion paper "Pole Fires due to Insulator Contamination"[1] to fully understand how one user approached the problem of reducing their troubles to a reasonable amount, utilizing the available insulators now on the market. Thus there was a large element of the so-called practical research applied to the problem in hand without attempting the development of new insulators. A definite problem existed, and it was necessary to know how much over-insulation would be required so that only one washing per year would be needed to prevent trouble.

The first necessity was a reproducible method of contaminating the surface of the insulators so that the results of successive tests would be comparable. A study of published information indicates a wide variety of test methods have been tried with a varied degree of success and failure. Methods with salt solutions applied to the insulator surface seemed erratic in results and were abandoned in favor of the fly ash and cement mixture which is described in the paper.

Some other authors have mentioned that the presence of water soluble compound is necessary for low-leakage resistance. It soon became apparent in our tests that completely water-soluble materials were partially washed off as soon as the fog condensed on the insulator, and erratic results were obtained. Less soluble material which retained the moisture and formed a conducting surface without being easily washed off was more successful in obtaining reproducible results.

While the test described by the authors is probably not representative of all kinds of contamination, it seemed to serve its purpose of being a reproducible test for laboratory comparisons of different insulators and various lengths of strings. The fog-wet flashover of the artificially contaminated insulators was not too far from that of naturally dirtied insulators, hence should serve as a good yardstick of performance under various conditions.

The papers by Frey[2] and Taylor[3] point out the need for further development in insulators to help solve some of these contamination and fog problems, and it is believed that one of the most important elements is further development of test methods so that the benefit of changes in design can be determined by laboratory tests that will really represent field conditions.

It would appear that the semiconducting glaze might be a major improvement if the manufacturing problems can be controlled. Reports from England indicate that insulators with such glaze have been satisfactory for cable terminals and apparatus, but little is known of the difficulties of obtaining such insulators.

In answer to Bellaschi's questions, records show that none of the flashovers of con-

taminated insulators occurred during switching operations. No records were obtained of leakage current discharges preceding flashover. There has been no indication that contaminated insulators were a source of undue radio noise. Earlier tests in the laboratory and field of the effect of discharges in causing radio noise showed rapid attenuation with increasing distance from the line.

Performance of Dust-Contaminated Insulators in Fog

BRADLEY COZZENS
MEMBER AIEE

T. M. BLAKESLEE
MEMBER AIEE

Synopsis: This paper presents a discussion of the problem of line insulator contamination by dust and the subsequent performance of the insulators in fog-laden atmospheres. A pioneer investigation of the subject carried out by the Department of Water and Power at Ryan High-Voltage Laboratory of Stanford University is described. Although the investigation was conducted in 1929, the information gained is still recognized as pertinent to the operation of transmission lines today. The quest for a trouble-free insulator for dust and fog areas still goes on while, in the meantime, periodic high-pressure water-stream washing of insulators, which followed the 1929 study of the problem and now is quite common practice, is an essential maintenance function to present operation.

THE detailed investigation of line-insulator performance described in this paper was prompted by experience with a 115-kv transmission line. A section of this line traversed a highly developed residential area. Audible noise and some radio noise which resulted from insulator sparking in fog-laden atmosphere brought complaints from residents of the area. This sparking in fog frequently resulted in flashovers with consequent line outages.

Published information on the subject was limited. Such data as were available in 1929 presented little discussion on the actual mechanism of dust deposition or on the arc formation that resulted from fog. It was felt that a thorough study of the problem might result in a better understanding of the situation and might possibly suggest an insulator design which would approach a solution to the problem. The data which were collected as a result of the investigation, though no longer new, still are fundamental and basic to the problem which currently is combated by the frequent washing of insulators.

Prior to 1929, the voltage distribution across insulator strings under dry conditions was considered of basic importance. Flashovers in fog were explained by water accumulating in large quantities on the insulators themselves and subsequently dripping past the units at the line end to initiate the arc. In the beginning of this study, close-range observations of insulators on transmission lines operating in fog-laden atmospheres were made which resulted in a somewhat different idea of the actual mechanism of flashover.

It was found that only one or two of the insulator units in a 7- or 9-unit string showed areas of visible corona or sparking, and at times these areas actually flashed over with limited-current arcs. These areas were located usually between the pin and the first petticoat of the insulator and the units were frequently, though not always, those near the line end of the string. Field observations made on these same insulator strings, operating in fog following a rain, revealed a somewhat different performance. Corona sometimes formed across areas on the top or edge of the insulator units in addition to the corona or sparking across areas on the under side of the units.

Preliminary attempts to study the problem in the laboratory by treating dust-coated insulators with fine water spray or with water vapor produced by boiling water in a small cabinet were made. It was evident, however, that more elaborate tests would have to be conducted to realize significant results and this led to the investigation described in this paper.

The Test Tunnel

Air movements existing at elevations of insulator strings on transmission towers in metropolitan areas carry turbulence; so, the tunnel used in the tests was not streamlined to produce uniformly smooth air flow. The test tunnel is shown in Figure 1. The centrifugal blower was capable of moving 140,000 cubic feet per minute. Six feet from the 5-foot 7-inch by 7-foot 4-inch fan outlet, the tunnel expanded to an 8-foot-square section. From this section to the test chamber, a distance of 20 feet, the sides of the tunnel were capable of giving an output opening adjustable to a maximum of 15 feet square. The final arrangement for the tests used an opening 15 feet high and 9 feet wide. Maximum wind velocity of 20 miles per hour was obtained through the test section with this size opening at the output of the tunnel.

Wind velocities below the maximum were obtained by restricting the air inlet into the fan. Vertical and horizontal vanes at the throat of the tunnel enabled some control of the uniformity of air flow across the test chamber. Synthetic dust flowed through a worm feed from a hopper into a $2^1/_2$-inch tube which opened in a vertical slot, 5 feet long, in the throat of the test tunnel. The dust flow from hopper through the tube and thence into the air stream was assisted by a small blower.

Dust

Since the immediate problem of the investigation was the study of the performance of the Department's (the Los Angeles Department of Water and Power) transmission lines, samples of dust which had

Paper 48-308, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted August 9, 1948; made available for printing September 7, 1948.

BRADLEY COZZENS and T. M. BLAKESLEE are both with the Department of Water and Power, Los Angeles, Calif.

The authors wish to acknowledge and express their appreciation for the assistance of Doctor J. S. Carroll and other members of the staff of Ryan High-Voltage Laboratory of Stanford University.

Figure 1. The test tunnel

accumulated on the insulators were obtained from two sections of the 115-kv transmission line to establish a basis for synthetic dust to be used in the experiments. The analyses of these two samples are presented in Table I. The sample from a section of the line adjacent to the railroad and to the Los Angeles River contained appreciable sulphur, petroleum products and carbon; the sample from a section of line in the San Fernando Valley, an agricultural area, was rich in organic materials and soluble salts. The make-up of the synthetic dust used in the tests is also shown in Table I.

Sodium, potassium, and calcium salts are the principal ingredients which contribute to the conducting properties of the dust layer when it is moist with fog. The synthetic dust was adjusted so that the conductance of an aqueous solution of the material was comparable to the same concentration of solution made with dust obtained from the line insulators.

It developed from the investigation, however, that aqueous solutions made from that part of the synthetic dust which accumulated on the test insulators carried slightly higher conductivity than the bulk material. This partially results from a mechanical and electrical separation occurring in the deposition process. Furthermore, difficulty was experienced as a result of the deliquescent property of some of the synthetic dust ingredients making it difficult to maintain the desirable dry, flocculent nature. It was necessary to heat the dust and maintain the admitting hopper warm in order to prevent compacting and clogging. For future tests, it is recommended that a dust composed of 50 per cent clay and 50 per cent feldspar plus sufficient powdered sodium chloride to produce the required conductivity be used.

Fog

Natural fogs are usually the result of condensation of water vapor around microscopic dust particles in the air and therefore may exist with humidities below the saturation point. With clean air it is possible to exceed 100 per cent relative humidity without the precipitation of fog.[1,2] In general, where hygroscopic particles are present in the air, fog is formed with 100 per cent relative humidity or at lower saturations.

The fog generator used in the tests was made up of a duplex high-pressure pump, an electrically heated boiler, and a series of nozzles. Distilled water from the pump was carried through the boiler where the temperature was raised to between 400 and 500 degrees Fahrenheit. It was then admitted into the lower section of the throat of the wind tunnel through a series of nozzles which produced a fine spray. The heat of the liquid at this pressure was sufficient to vaporize a large portion of the water coming out of the nozzles, thereby raising the relative humidity of the proximate air. The remaining water was broken up into finely divided particles by the swirling action of the nozzles to produce the artificial fog. So completely was the heat of the liquid used up, that the fog so produced was approximately at the temperature of the surrounding air by the time it was three feet from the nozzles.

The low day-time relative humidities of the Palo Alto climate made it necessary to conduct the fog tests at night to avoid evaporation of the artificial fog as it drifted down the tunnel to the test chamber. At night, with relative humidities of approximately 80 per cent, the fog generated was quite satisfactory. A slight opening in the intake of the fan was usually sufficient to cause a drift of fog from the nozzles across the insulators in the test chamber; the fan was not operated for fog application.

Measurement of Leakage Current

Leakage current over the insulator string was of particular interest as a measure of contamination and likelihood of arcover. The cable supporting the test insulator string was fitted with a special insulator above and outside the test chamber in such a position that it was not easily contaminated by dust or wetted with artificial fog. This permitted the leakage current over the test string to be carried to ground through a magnetic oscillograph element which recorded the current on 35-millimeter film. The current was recorded continuously from the time the fog was applied until some minutes after it dispersed and spitting and arcing over the insulator string subsided. Figure 2 shows a sample of film record.

A method of coding information on the film was employed using a second oscillograph element. It was thus possible for the observer to indicate which unit in the string was arcing, the severity of arcing, and other pertinent information, and thereby obtain a correlation between observed data and leakage current. Also other deflections of the coding element were applied automatically by a synchronous clock to indicate the duration of test.

Test Procedure

Considerable work was performed initially in the effort to establish a test procedure of dust application that would duplicate closely conditions observed on transmission lines. It was soon discovered that the pattern of the dust deposit is related to wind velocity. Dust blown at low velocity precipitates largely on the tops of the insulators while high-velocity wind deposits more dust on the under sides of the units.

Table I. Analysis of Insulator Dust

		Per Cent
Dust from 115-kv Transmission-Line Insulators Adjacent to Railroad Right of Way

The preliminary studies showed that proper deposition of dust could be obtained only with the insulators subjected to normal operating voltage while the dust was being blown by. The deposits of dust under energized conditions were concentrated around the pin; without energization the deposit was more uniformly distributed on the under sides of the insulators.

Laboratory observations of dust dropped between plates carrying an alternating potential difference show that many dust particles blown into the air carry electrical charges. Such charged dust particles passing an energized insulator string may be attracted and deposited upon, or adjacent to, the pin or cap of the insulator. Insulator pins operate frequently with a small amount of corona especially when in a moderately high-velocity wind stream. The space charge produced by this corona travels out at high speed. Thus, dust traveling at 20 miles per hour (4 inches per half cycle at 60 cycles per second) may receive a charge of one polarity while three or four inches in space from the insulator pin. On the succeeding half cycle, with reversal of charge on the pin, the dust particle is attracted to and may deposit about the pin to give the characteristic dust pattern found on energized insulator units in service.

Dust applications were made with wind moving at 20 miles per hour and also at 3 miles per hour; the latter wind velocity was used to produce a deposit of dust on the tops of the insulators. The test procedure adopted resulted in the depositing of a little more dust on the top surfaces of the insulators than is usually found in practice. However, since the top surfaces are easily cleaned by rain, and, since, in the test setup, this top surface dust was easily leached by the artificial fog, this difference in test conditions from practice was not considered serious.

The standard string consisted of nine units where the pitch was $5^3/_4$ inches or less; for units with larger pitch, the string lengths were maintained between 45 and 50 inches. All strings were energized with 76.4 kv to ground, in order to subject them to the normal operating voltage of the Department's 138-kv system.

The standard test for the various insulator strings covered by the investigation consisted of five dust and fog periods as outlined below:

First Period

Three pounds of dust blown through the tunnel at 20 miles per hour.

Two pounds of dust blown through the tunnel at three miles per hour.

Five minutes of fog.

Ten minutes of wind at 20 miles per hour to dry units.

Second Period

Units given the same treatment as first period.

Third Period

Units given the same treatment as first period.

Fourth Period

Five pounds of dust blown through the tunnel at 20 miles per hour.

Three pounds of dust blown through the tunnel at three miles per hour.

Ten minutes of fog.

Ten minutes of wind at 20 miles per hour to dry units.

Fifth Period

Five pounds of dust blown through the tunnel at 20 miles per hour.

Three pounds of dust blown through the tunnel at three miles per hour.

Forty minutes of fog with the last ten minutes of this fog period made exceptionally heavy.

A collection was made of practically all the standard shapes of suspension-type insulators available at the time, and, in addition, experimental insulators were made from twelve special patterns. The patterns included five modifications of the standard unit, which eliminated successively the petticoats progressing from the pin to the outer edge of the unit, and 10-inch diameter flat units with various numbers of very small petticoats or protrusions on the bottom surfaces. Another series of patterns varied the pin size from 1/2 inch to $1^1/_2$ inch and used a porcelain disk with a small bead on the outer rim. A string of insulators using old 12-inch diameter flat Thomas disks, assembled with modern cap-and-pin hardware, was made up in the laboratory and subjected to the dust and fog tests. Cross-section diagrams of most of the suspension units tested are shown in Figure 3.

Discussion of Test Results

Insulator strings subjected to the full test procedure, or sometimes only four cycles of dust and fog applications gave leakage currents varying from 50 to 100 milliamperes when in the fog cycle. Units of the conventional type flashed over usually before the leakage current reached 100 milliamperes. It was concluded that insulators in such a con-

Figure 2. Samples of 35-millimeter film record of leakage current and coding trace

taminated condition and operating on actual transmission lines in fog will flashover when the leakage current reaches 50 to 60 milliamperes. In the limited test period of a few minutes, the various probabilities do not always combine to allow flashover to take place. It was very rare, however, that insulator leakage currents reached 100 milliamperes without resulting in flashover. Large insulators or insulators with deeply grooved skirts, however, generally carried higher currents without flashover than the smaller standard units.

The color of the sparking on insulators may be indicative of the performance of the string, although this fails sometimes because of the coloring caused by deposited salts. A blue sparking on the units generally indicates that the insulator string is performing satisfactorily. When the arcs across dry areas adjacent to the pins are deep yellowish or reddish, the current is probably in excess of 25 milliamperes, and the string is approaching the threshold of flashover.

The tests and observations of the performance of many line insulators through the cycles of dust and fog applications resulted in a good understanding of their performance under such conditions. The normal voltage distribution over a dry dust-covered insulator string that exists as a result of the electrostatic capacitances of the units is upset as soon as fog moistens the dust layer. When moist, the normal capacitance current of one or two milliamperes is masked by the leakage current as the moist layer of conducting

Figure 3. Insulator types tested

dust turns the insulator string into a series resistance from line to ground.

The resistances of the various sections of this series circuit may not be uniform over the entire insulator string, resulting in a nonuniform voltage and energy distribution. Even with a uniform dust coating and wetting, the increased current densities adjacent to the cap and pin will cause increased voltage drop and increased heating and drying in these areas. Even with heavier dust deposits adjacent to the pins and caps these areas usually carry the bulk of the voltage. Since the distance over these areas is usually small, the areas are highly stressed and break into corona or become evident by surface sparking. The sparking results from capacitance discharges, but arcs of higher current occur occasionally over these dry areas. The current is, of course, limited by the series elements of wet film on the insulators. The wet sections, which are carrying little or none of the applied voltage, appear dark in contrast with the dry corona-covered or sparking areas.

As a further proof of this uneven voltage distribution over dust-covered and moist suspension insulator units, actual voltage gradients were determined in this investigation with a high-voltage potentiometer. These determinations were made using a method developed by Doctor J. S. Carroll of Stanford University which employs a sensitive electroscope as the indicator of voltage balance with the potentiometer. The curves of Figure 4 prevent the results. Curve *1* is theoretical, calculated on the premise of a uniform coating and wetting over the entire insulator surface. Curve *2* is a theoretical curve in which the surface resistance per unit area is assumed proportional to the distance out from the pin. This is somewhat in line with the actual condition as the heavier deposit of dust near the pin (a condition that always obtains as explained previously) reduces the resistance over this area upon initial wetting as compared with the resistance at the outer edge of the porcelain. When drying starts this conditon is completely disturbed.

Curve *3* presents the measured voltage distribution found over an insulator removed from a transmission line in the vicinity of Los Angeles. This potential-gradient determination was made with 2,000 volts applied across the unit. This voltage was not sufficient to produce significant drying of the moist dust film and consequently the curve represents the distribution over relatively uniformly moistened surface of an insulator which had accumulated contamination in actual transmission-line service. Very little potential drop appeared across the first six inches from the pin; this gave definite proof of the heavy dust accumulation that occurs adjacent to the pin as a result of electrical precipitation.

Curve *5* represents the distribution over a similar unit taken with 10,000 volts impressed. In this case, 40 per cent of the voltage appeared across the first half inch from the pin, in spite of the heavier contamination in this area which was indicated by curve *3*. Progressing outward from this area, the voltage gradient was low until, at the clean outer edge of the porcelain, appreciable voltage drop was sustained. There was practically no voltage drop over the top surface except at the area immediately adjacent to the cap. The 10,000 volts impressed across this unit caused sufficient current to dry the areas adjacent to the pin and cap forcing these areas to carry large percentages of the total voltage.

Curves *4* and *6* show voltage distributions across an insulator unit which had been subjected to the first period of dust deposition in the test procedure; the distributions were made with 2,000 and 10,000 volts respectively to give comparative data for curves *3* and *5*. The similarity between curves *2* and *4* demonstrates the close approach of the test procedure dust application to the situation as it occurs in actual practice. Curve *6*, for 10,000 volts applied, shows that 97 per cent of the voltage was carried by the first $1^1/_2$ inches of insulator surface adjacent to the pin. This situation bears out the basic reasoning behind the explanation of the cause of the observed performance of insulators operating under dust and fog conditions.

Variations of dust consistency in the air stream and the general erratic action of insulators under dust and fog conditions make it difficult to give an absolute statement regarding the relative effectiveness of the various insulators tested. For example, the study of the effect of pin size revealed little difference between the performance with 1/2-inch pins and the $1^1/_2$-inch pins. Minor changes in petticoat dimensions produced no measurable difference in performance.

Insulator-Washing Tests

Early in the investigations described in this paper, it was realized that the development of an insulator that would be the answer to the dust and fog problem would not be possible in a short period. It was obvious, however, that the problem could be solved by keeping the insulators clean. Efforts were concentrated on the development of an improved method for cleaning insulators, one that would be cheap and still be effective. Thus, the 1929 tests at Ryan High-Voltage Laboratory included insulator-washing experiments.

Insulators were removed from lines in actual service and transported to the test tunnel where they were subjected to the normal application of artificial fog to obtain a measure of the degree of contamination. Many of these insulators showed leakage currents as high as 35 milliamperes. The insulators were then washed under various procedures using nozzle-directed water streams at nozzle pressures ranging from 200 to 500 pounds per square inch. The nozzle used had a 3/32-inch aperture.

It was not difficult to remove most of ths soluble materials from insulators contaminated with dust from sandy-loam agricultural areas, but it was not possible to clean completely the surfaces or to remove all soluble material from insulators contaminated with soot and smoke as a result of locations adjacent to railroad rights of way. In both cases, however, the leakage currents over the insulators when operated in fog were materially reduced from the values for corresponding circumstances when dirty. The dust-contaminated insulator leakage current was reduced to less than two milliamperes and the soot-contaminated units showed a corresponding reduction to about three milliamperes. Neither of these current values is sufficient to result in appreciable sparking, and both are well below values which are in danger of resulting in flashover. It was apparent that high-pressure water-stream washing of insulators would insure safe operation of the units for some period of time. A periodic maintenance operation was thus established as a solution to the insulator contamination problem.

There then followed the development of insulator-washing equipment to facilitate this maintenance operation. One of the insulator-washing trucks used by the Department for routine cleaning of pin-type and suspension insulators is shown in Figure 5.

The truck is equipped with water tank, high-pressure pump, and an 85-foot fire-type extension ladder. Pres-

ent practice is to use positive-displacement pumps with regulator valves producing pressures up to 1,000 pounds per square inch at the pumps and capable of delivering 50 gallons per minute. Long tapered nozzles are used with openings up to 1/4-inch diameter. Many improvements in nozzle design and construction are described in a paper by G. Leslie Hill.[3] The ladder on the truck permits raising the man and nozzle to sufficient elevations to properly wash insulators on the majority of 34.5-, 115-, and 138-kv circuits. The taller 287.5-kv towers are provided with piping from base to insulator levels where taps are provided for attaching a short section of hose with the directing nozzle. The high-pressure water output of the washing truck connects to the piping at the tower base.

Washing schedules were established after an extensive survey and check of conditions on transmission lines operating in and adjacent to Los Angeles. The 34.5-kv distribution circuits and the 115- and 138-kv transmission circuits are washed at three-month intervals and the 287.5-kv circuits are washed every six months in residential areas only.

Where duplicate circuits and loads permit, insulators are de-energized for washing. At first the washing of energized units was performed only on 34.5-kv circuits, but this practice was soon extended to all voltages including 287.5 kv. Before extending the operation to the higher voltages, however, extensive tests were conducted to determine the current through the nozzle stream under various water pressures and for various distances from the energized parts. This ground has also been thoroughly covered by Hill.[3] Washing is not carried on normally with distances less than 15 feet between nozzle and energized circuit.

Conclusions

The voltage distribution over contaminated insulators operating in fog is determined by the leakage current flowing over the insulator surfaces, and any normal capacitance-controlled voltage distribution is masked by this resistance-controlled voltage division. As a result of heat developed over sections of the insulator surface resistance, certain areas of the insulators dry rapidly increasing the resistance of such areas and forcing them to take large portions of the total voltage across the insulator string. The dry areas become overstressed and therefore exhibit corona, sparking, or occasionally flashover to give higher leakage currents that are limited only by the resistance offered by what damp sections of insulator surface remain.

Test procedures can be established which will produce results quite comparable with experiences in actual practice. The results of such tests have indicated little, if any, superiority in performance of the various existing conventional designs of insulator units. The 12-inch flat disk-type insulator shows a slight superiority, but the excessive corona and resultant radio disturbance and audible noise precludes its use in thickly populated areas.

The washing of insulators with clear, high-pressure water jets at regular intervals, established as required in accordance with the extent of dust accumulations and the frequency of fog occurrences, can result in overhead, high-voltage line operation free of flashovers from dust and fog. Observations of local conditions of the audible noise level and the nature of arcing on insulators can be used as criteria for determining when it is necessary to start insulator washing to prevent flashovers.

Discussion

P. L. Bellaschi (Consulting Engineer, Sharon, Pa.): Insulator contamination is a problem which confronts engineers in many lands. Although considerable progress has been made in recent years, the problems it presents have not been completely solved as yet. We are fortunate, therefore, in having the more recent findings, as well as the general subject, reviewed at this time.

In the course of an engineering trip throughout South America several years ago, this problem was brought to my attention repeatedly. Because of limited space, I shall confine myself here to a typical instance with reference, specifically, to the difficulties encountered in the São Paulo region in 1944.

São Paulo lies inland some 50 miles from the sea on a plateau at about 2,000 feet (600 meters) elevation. The land rises abruptly from the seashore to the upper lands. Transmission lines (80 kv) from the hydroplants near sea level negotiate the bluff, then continue inland on the plateau to São Paulo. The lines are of steel tower construction and were insulated with four suspension insulators at the time. The operating voltage is 80 kv line to line (46 kv to ground). The dry flashover voltage being in the order of 250 kv, ratio between operating voltage and dry flashover is about 0.20.

Along the bluff, due to the warm humid air rising up to the plateau, the insulators are drenched year round and present no problem. On the plain, the rain comes at frequent intervals except for the dry season which lasts some three to four months—from May to August. During this period, the insulators of the lines on the plateau accumulate dust. The presence of new factories in the São Paulo region during the war further contributed in some measure to the contamination problem.

In 1944, the dry season had been unduly hot, and the rains were fully a month overdue. Coupled with these conditions, this was the time (September-October) of heavy fogs. Starting in the evening, the fog would roll up from the sea across the plateau, and by early morning, occasional flashovers would follow. For instance, on August 18, between 5:40 and 7:15 a.m., seven line outages were recorded. Under these conditions of combined dust, industrial contamination, and heavy fog, insulators that normally had a flashover strength of 250 kv would suffer a drastic reduction down to less

than 20 per cent (46 kv, the operating voltage), with the result that copious flashovers would result at operating voltage. Under these adverse conditions, and in spite of some attempt at cleaning, there were a total of some 20 or more outages recorded in the course of a few weeks.

At the main hydrostation as well as at other generating stations, the neutral is solidly grounded but at the receiving stations (near São Paulo) neutrals are grounded through 100 ohms. The result of this was that when an insulator string would flashover, due to the overvoltages developed from the arcover propagated to the entire system, these overvoltages would induce flashover on other parts of the system because of a general lowering of the insulation throughout the system. For instance, at 6:40 a.m. on September 28, six of the lines tripped, at intervals possibly some twenty or forty cycles, and even more, apart, according to the oscillographic records. During this period, a number of flashovers had occurred in the main receiving station.

In one instance, this station was de-energized in order to repair the damage. When all had been cleared and an attempt made to re-energize the bus, the insulation would not sustain the voltage. During the shutdown, the fog had completely wetted the insulation. Half an hour later, at 5:00 a.m., conditions apparently became more favorable and it was possible to return the station in service. Judging from the noise and pronounced sparking on the bus insulators, the leakage currents certainly must have been relatively high, gradually subsiding as the insulators dried out.

Under these circumstances, it was apparent that four suspension insulators resulted in a "tight situation." More liberal insulation was recommended. A cleaning and washing program of the insulators on the line and in the station was instituted.

I would like to ask the authors of the paper whether switching surges superimposed on the sustained 60-cycle operating voltage might not have precipitated some of the flashovers experienced on their system. If such should be the case, then a long sustained 60-cycle voltage with switching overvoltages superimposed thereon might well be a test of significance to consider in investigations of this character. In any event, it would seem that the 60-cycle test voltage should be sustained for a reasonably long period of time.

Have the authors observed either by cathode-ray oscillograph records, or otherwise, abrupt leakage current discharges preceding and possibly precipitating flashover?

I would like to ask the authors whether, in their view, cleaning of the insulators under conditions of severe contamination as discussed here might not be predicated equally as much by radio-noise considerations in addition to the potential flashover hazard? Have radio-noise tests been conducted in the field and in the laboratory under these conditions?

The authors might find of pertinent interest the various contributions by W. Wanger presented at the International Conference on High Voltage Electric Systems in 1939 and later in Brown Boveri Review.[1,2] Perhaps he was the first to investigate the relative effect of voltage duration on the flashover of contaminated insulators. Investigations conducted by the writer on insulators subjected to chilling in dry ice (CO_2) and then exposed to a humid atmosphere, and subjected, subsequently, to impulse, switching, and 60-cycle voltages confirm the work by Wanger generally well. The 60-cycle strength can well be reduced to 20 per cent of the dry strength, especially if the porcelain surface is contaminated. The impulse strength is not affected as much. The switching-surge strength is intermediate; the amount the insulation strength is lowered depending on the duration. Dew and fog in combination with contamination in general present the worst condition.

In view of the increasing importance of the problem and the fact that we have not yet completely solved it, it would be well for the transmission and distribution committee to continue giving its attention to this matter.

Bradley Cozzens and T. M. Blakeslee: Bellaschi has discussed a condition existing in South America which is not entirely unlike that found in southern California and other west coast areas. Extended dry periods, where conducting dust is precipitated upon the insulator surfaces, either with or without alternate periods of condensation to cement the dust into place, followed by periods of heavy fog or mist appear to be the most serious in causing flashover.

The Boulder transmission line of the Department of Water and Power is washed regularly through the populated area, but, at a location approximately seven miles from the Los Angeles terminus, washing was not practiced for the first ten years of operation. A relatively long dry period, extending from March to September 1946, allowed heavy accumulations of dust to develop, so that when the first fog actually did occur, flashovers were frequent.

It was on this occasion that it became necessary to wash the 287-kv transmission circuit for an additional seven miles while the circuit was energized.

Replying specifically to the questions of Bellaschi, switching surges most certainly would tend to precipitate or initiate flashover of a contaminated insulator string operating in fog. Strings severely contaminated operate with but small areas of the insulator surface dry and carrying practically all of the line to ground voltage. The application of the surge would, of course, flashover these dry areas probably on many of the insulator strings, and, on some strings, the remaining surface resistance would not be sufficient to limit the follow-up arcing current to a sufficiently low value to prevent flashover.

Regarding the suggestion of this procedure as a method of test, such a procedure might lend considerable information to the art of testing insulators in fog, but, on the transmission lines, where several hundred insulator strings are involved, it is again a matter of probability as to which string will flashover, and laboratory testing on this basis would be relatively difficult, particularly from a statistical standpoint.

Regarding the second question as to observation with a cathode-ray oscillograph, such records have been obtained by other authors, but the authors of this paper have confined their measurements to normal magnetic oscillograph records. From the mechanism involved, however, it is practically certain that each flashover which occurs is the result of cascade action, namely, the flashover of one dry area throwing additional voltage on to the dry areas of other units in the insulator string with ultimate breakdown of the entire string.

Regarding the third question by Bellaschi as to whether or not radio noise might be a measure or criteria for determining the cleaning of insulators, it has been our observation that the radio-noise level depends very materially upon the degree of wetting of the insulator surface and to some extent upon the nature of the contamination. After wetting has continued for a period of hours, the insulators may become relatively quiet both audibly and electrically, and only an intermittent spit or buzz in a radio receiver will result. On the other hand, under certain very adverse conditions, dry areas may be formed immediately adjacent to the cap or the pin of the insulator, and practically continuous capacitance discharge exists between the edge of the wetted surface and the metal parts. When this exists, the radio noise is very evident and can be recorded for some distance from the tower upon which the disturbance occurs. It has been our observation, however, that this condition may occur when the maximum leakage current might still be limited to 10 or 15 milliamperes while a much more severely contaminated insulator might fail to develop radio noise. A study of the noise patterns developed as a result of various degrees of contamination might eventually yield a method of measurement as a basis upon which to determine when insulators should be washed.

Bellaschi's discussion again serves to indicate that the problem is not limited to isolated areas, but is relatively universal in its extent, as indicated in our paper.

Voltage Surges in Relay Control Circuits

T. R. HALMAN
MEMBER AIEE

L. K. HARRIS
MEMBER AIEE

THE SUPREME importance of protective relays is universally recognized and much engineering study is devoted to their design, manufacture, application, and maintenance. By comparison the battery and control circuits, being less spectacular and inherently less complex, may appear to require but superficial attention. Nevertheless great care is justified in the planning, installing, and maintaining of station controls to obtain the utmost reliability. The battery with its associated control elements actually occupies a position of major importance in a station, first because its failure would put the entire station control out of commission, and second because all of the station d-c control wires are brought together at its positive and negative terminals or at busses connected thereto, and through these, troubles can be communicated from one part of the station to another. It is common practice to separate and isolate the positive and negative busses, fuse branch circuits to disconnect them before local trouble can spread to the whole station control, and to ground the control system at one point only and then through lamps so that a ground on either the positive or negative side will not cause a short circuit on the battery, but will immediately give an indication or alarm. Control circuits are usually well isolated from the high-voltage lines, which they control, and are little influenced by potential transients due to lightning, high-voltage switching, or fault currents. They are, however, subjected to high-voltage surges which are caused by the discharge of energy stored in the magnetic fields of inductive devices which are connected to them. This paper deals with problems concerning these voltages and with methods for their control and suppression. The material and ideas which are presented have been gleaned to a large extent from experiences and operating practices of the company with which the authors are associated. The proposed methods of control and suppression may not be readily applicable to all schemes of d-c control, but it is believed that the ideas to be presented are sufficiently inclusive to merit general consideration.

Insulation stresses, due to the de-energizing of inductive circuits, well above the value deemed safe for periodic testing are often encountered. Voltages as high as 5 kv have been recorded during the discharge of small 125-volt relays and by paralleling the coil with a small capacitor (100–200 micromicrofarad), thus simulating the effect of the capacitance of a short length of control wire, voltages as high as 7 kv were measured. Lower surge voltages usually accompany the discharge of large devices such as the coils of the solenoids used to close large circuit breakers, however, the energy is always much greater. Transients in excess of 1,700 volts have been obtained from the de-energizing of 125-volt solenoid closing coils and 2,500 volts from 250-volt closing coils.

Uncontrolled voltages of this order of magnitude on the battery and control circuits of a station may result in injury to personnel, unnecessary service interruptions, and equipment damage. Any of the larger inductive devices such as circuit breaker closing solenoids, tractive and lifting magnets, and machine fields discharge sufficient energy and at proper voltage and duration to cause severe and possibly fatal electric shock. If a ground exists in the solenoid coil, the control contactor, or the intervening wire, or is caused by the discharge transient, it will expose the entire station control to a high voltage. Such a voltage surge, when imposed on the control wiring of a station, in seeking the easiest path to ground may break down the insulation of relays, current transformers, terminal blocks, and wiring and in discharging to ground, trip operating lines with consequent unwanted equipment outages and service interruptions. Equipment damage in itself is usually less serious than the other types of trouble. However, it is often difficult to locate, and until found and corrected, will remain a potential hazard which could become serious at any time. Repairs may lead to an extensive and expensive program of preventive maintenance in the form of repairing, altering, or replacing all pieces of equipment of a certain type which has proved vulnerable.

The elements of a typical control circuit are shown in Figure 1. When the contacts are closed, the current through the inductive circuit of the coil rises to a value determined by the voltage of the battery and the resistance of the entire circuit. The instantaneous current at any time t is determined from a solution of the differential equation of the circuit.

$$E = iR + L di/dt \qquad (1)$$

The solution of this equation is complicated by the fact that the inductance L in such an iron path is a function of both current and armature travel and that the resistance R is influenced by iron losses in the core material. A solution useful for approximate results is obtained by assuming the circuit parameters to be constant. This leads to the familiar equation

Figure 1. Schematic diagram of typical circuit breaker closing circuit

Paper 48-309, recommended by the AIEE relay committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted August 4, 1948; made available for printing September 8, 1948.

T. R. HALMAN and L. K. HARRIS are both with The Detroit Edison Company, Detroit, Mich.

Figure 2. Schematic wiring diagram of a circuit breaker being operated, another similar circuit breaker, and instantaneous relay circuit of a bus protective scheme

Potential at A and A_1 is −60 volts. Potential at B and B_1 is 60 volts. Assume 2,000 volts induced in closing coil by collapsing flux. Potential at C is −2,060 volts. Voltage across contactor is 2,120 volts

$$i = E/R\left(1 - \epsilon^{-\frac{Rt}{L}}\right) \qquad (2)$$

The time constant of relays is very short and even with the solenoids used to close large circuit breakers, the work cycle is completed and the current substantially constant in less than one second. As the contactor opens, it draws an arc which acts as a series resistance in the circuit thus expediting the decay of the current through the closing coil and the flux linking it. The transient voltage which accompanies the opening of the coil circuit of an inductive device is due to the rapid transfer to the electric circuit of energy which has been stored in the magnetic circuit. In accordance with Lenz's law, the decaying flux induces a voltage in the coil which tends to keep the current constant and in the same direction. The magnitude of the induced voltage is given by the fundamental relation

$$e = -L\,di/dt \qquad (3)$$

The solenoid, which has been receiving energy from the battery, becomes a source as soon as the current starts to decrease, and since the direction of current does not change, the potential polarity of the solenoid reverses. Normally the circuit through the ground lamps holds the battery terminals at a fixed potential with respect to ground; the negative terminal and the end of the coil connected thereto having a potential of negative 60 volts. Starting at the normally negative terminal of the coil and proceeding through it, the induced voltage causes the potential to become more negative until the other terminal, the contactor terminal, and the intervening wire will be negative with re-

Figure 3. Schematic wiring diagram of a circuit breaker being operated, another similar circuit breaker, and instantaneous relay circuit of a bus protective scheme

Figure 6 (right). Oscillogram of transient voltage build-up across relay contacts with capacitance to ground of opening wire exaggerated

spect to ground by an amount equal to the sum of the induced voltage and one-half of the battery voltage. Since the sum of all of the voltages around the circuit must be zero, there is a voltage of opposite polarity equal to the sum of the induced and battery potentials across the opening contacts of the control contactor. This condition is shown in Figure 2, which is a schematic wiring diagram of the control of the circuit breaker which is operating, one similar circuit breaker position, and the current transformer and instantaneous over-current relays of a bus protective scheme

Figure 3 shows the same control wiring but with a ground at the contactor terminal of the closing coil, either existing previously or occurring due to the discharge voltage of the coil. This is the only point subjected to extreme potential to ground until breakdown occurs. Unless other unintentional grounds exist, the entire station control now becomes positive with respect to ground by an amount approximately equal to the discharge voltage. Usually the first noticeable effect of such a ground is the violent destruction of the ground lamps. Their filaments are burned out and their glass envelopes often are broken and occasionally blown from their bases. In Figure 3 several parts of the control wiring are shown at ground potential in turn due to grounds which may already exist but more probably are caused by insulation breakdown resulting from the surge voltage. Assume a ground at point 1 which may be any place between the closing switch and the coil of the closing contactor. The contactor will be energized and will reconnect the closing coil to the battery thus suppressing the surge voltage immediately. Should both grounds persist, the contactor will remain closed and the closing coil will be destroyed unless successfully protected by fuses, which is difficult, however, should the restoration of near normal potential by the closing of the contactor free one or both of the grounds, the contactor will drop out, initiating another discharge surge, again energizing the contactor, thus causing a rapid pumping of the solenoid. Should this ground occur at point 1A in the closing circuit of another position, it would energize the closing coil of a closed circuit breaker or close an open circuit breaker. This latter could result in serious injury and equipment damage, for example, if the circuit breaker put a large standing machine across the line especially if it were done while an operator was opening or closing disconnect switches. A fault of this type

Figure 5. Oscillogram of transient voltage build-up across relay contacts with normal circuit constants

Figure 7. Oscillogram of discharge transient of 125-volt relay

Figure 8. Rectifier used to suppress discharge voltage

was experienced while starting a 400-horsepower 250-volt d-c motor which drives a water circulating pump. The normal starting sequence is to close the positive circuit breaker, decrease resistance across the negative circuit breaker in steps to bring the motor up to speed, and finally close the negative circuit breaker. The discharge voltage of the closing coil of the positive circuit breaker caused a ground on the closing wire of the negative circuit breaker thus energizing the closing contactor and closing the negative circuit breaker. The motor, being thrown directly across the line, received a severely burned commutator and badly dislocated commutating field coils, one of which was forced against a shunt field connection with sufficient violence to sever the connection and open the shunt field.

A ground at point 2 would energize the opening coil of the closing circuit breaker resulting in an apparent trip-free operation. A similar ground on another position, point 2A, would open a closed circuit breaker and could interrupt service. Either of these grounds would destroy the pilot light which monitors the opening circuit and indicates the closed position of the circuit breaker. Another type of fault caused by solenoid discharge voltage shows a breakdown of insulation at point 3 between the contact and coil circuit of a protective relay. In the case illustrated, the relay is in a bus protective scheme and the return path is through the relays and current transformer to the current-transformer ground. This particular fault occurred in a major switching station,

Figure 10. Resistor used to suppress discharge voltage

opening nearly all of the lines on a large bus, and interrupting service to a number of large customers.

Some investigators have reported that the electrostatic capacitance of control circuits materially influences the discharge voltage of inductive devices.[1] The capacitance-to-ground of the d-c control circuits of some typical switching stations was measured and found to vary from 0.05 microfarad for a small indoor substation, using rubber-covered wire in steel conduit for control, to 6.0 microfarads for a large outdoor station having many long runs of lead-covered control cable. Taking these values as representative, a study was made to determine their effect on the discharge voltage of both solenoids and control relays. By referring to Figure 1, it is seen that the measured capacity is divided into two parts, one between the positive bus and ground, and the other between the negative and ground. Considering the closing solenoid with no unintentional ground on the control circuit, the only effective capacitance subjected to high voltage is that of the positive part of the closing coil itself, one terminal of the contactor and the intervening wire, a value too small to produce a measureable effect. A ground on the positive terminal of the closing coil, however, ties this point to the common of the two capacitances, whose other terminals are connected together through the battery, and the induced voltage of the coil charges them to a high potential.

The capacitances involved consist of a large number of small distributed values connected in parallel to each of the control busses. An inspection of the shape of the discharge voltage wave shows the rate of change of voltage with respect to time to be low enough to permit the substitution of lumped capacitors for the distributed capacitance. The effect of capacity on discharge voltage has been analyzed and a mathematical treatment of it presented elsewhere.[2] Analysis of a large number of tests, made with different closing solenoids and with capacitors varying from zero to 6 microfarads, showed that this amount of capacity had no material effect on the peak voltage of the discharge, although it did alter the wave form by making the tail steeper and oscillatory.

The results obtained with relays were less uniform. In general the presence of capacitance paralleling either the relay coil or the de-energizing contacts decreases the discharge voltage. There appears to be a critical value, which for most 125-volt control relays is quite low, that increases the discharge voltage. One relay having a 2,000-ohm coil with a normal discharge voltage of 5 kv when de-energized by a snap switch, while less consistant, gave values as high as 7 kv when supplied through a short length of coaxial cable which had a capacitance of approximately 200 micromicrofarads. Should a breakdown to ground occur so that the capacitance of the station control as well as the ground detector lamp parallels the relay coil, the discharge voltage is effectively reduced. Due to the relatively small amount of energy involved, the discharge voltage of control relays and even opening coils of circuit breaker operating solenoids does not present as serious a problem as does the discharge voltage of closing coils.

Many of the high-speed protective re-

Figure 9. Oscillogram of discharge transient of closing coil suppressed by rectifier

Figure 12. Teaser electrode used to suppress discharge voltage

lays must have their contacts adjusted to a very small gap and there is considerable interest and some apprehension as to the magnitude and effect of the potential which appears across the open contacts during the discharge of an inductive device. Tests which have been made by manufacturers of protective relays show that with a contact spacing of 0.010 inch the 60-cycle rms breakdown voltage will exceed 1,000 volts. Figure 4 shows the conventional method of connecting a circuit breaker operating solenoid. With only the battery lamps grounded, the interruption of closing coil current will not alter the potential at either terminal of the opening coil circuit and the voltage across the protective relay contacts will remain equal to control battery voltage. With a ground at point A so that the surge voltage raises the entire battery and control wiring to a high potential above ground, the potentials at points B and C again differ by the battery voltage. Since the inductance and capacitance of the wire between B and the positive contact of the relay is low, the capacitance will charge rapidly without oscillation and the potential at the positive contact will be very near the same as at B at all times. In the opening coil side of the circuit the small capacitance of the opening wire must charge through the high inductance of the opening coil. With a suddenly applied voltage, the circuit oscillates and a voltage equal to the battery voltage plus the peak voltage of the oscillatory wave will exist across the open contacts. Figures 5 and 6 are oscillograms showing this voltage to be moderate and with contact spacings of not less than 0.010 inch no breakdowns are expected.

Methods of Surge Voltage Suppression

Equation 3 may be rewritten:

$$e = kN^2 di/dt \qquad (4)$$

The factors which make up k, that is the size, shape, and material of the magnetic circuit are determined within reasonable limits by the characteristics of the load including total work, force-travel relations, and frequency of operation, and to a less extent by cost and efficiency. These same factors conjointly with the source voltage also determine the size of the coil wire and the number of turns, N. Since both k and N are fixed by design considerations, the factor di/dt affords the most ready means of controlling the discharge voltage. The current in this factor includes currents which are induced in the magnetic material and in contiguous conducting parts as well as the current in the coil itself. Any decrease in di/dt will increase the time interval between the removal of the supply voltage and the drop-out of the device; in other words the flux requires a longer time to decay to the pull-out value. In some relay applications it may be undesirable to retard the opening, however, this is not generally true. In the circuit breaker closing problem, a trip-free opening followed by an immediate reclosure is the only operating sequence, so far conceived, which is likely to be adversely affected by decreasing the rate of current decay. Such a requirement is not considered imminent. As a sudden decrease or interruption of the coil current of a solenoid having a solid iron magnetic circuit causes the transfer of a large proportion of the ampere turns to the iron, it follows that any modification of the core iron to obtain faster closing, which may vary from a single radial plunger slot to complete lamination of the iron, will increase the time rate of current decay and consequently the induced voltage. To summarize, any design intended to increase pick-up speed by expediting the build up of the flux will usually encourage its rapid collapse. Several methods for decreasing the rate of current decay are suggested and most have been proved in service.

Dry-Plate Rectifier

The functioning of a one-half wave rectifier to suppress the discharge voltage of an inductive device is predicated on the reversal of potential polarity at the inception of the discharge. The device is connected in parallel with the coil as shown in Figure 8. It presents a high resistance to the flow of current while the coil is energized and a low resistance to the discharge current which flows through it in the opposite direction. The arrows show the direction of the current during the discharge. All of the types of dry-plate rectifiers work satisfactorily provided they have sufficient plate area and number of junctions. The authors have had considerable experience with this application of rectifiers and believe that the method has several advantages over any other that has come to their attention. Rectifiers are very effective as voltage suppressing media, limiting the discharge voltage to less than operating voltage, do not add appreciable load to the current source, materially decrease contactor duty and maintenance, and have long trouble-free lives. About 500 of these devices were installed on large solenoids before the war and an equal number since war-time restrictions were removed. There have been approximately five failures all due to increase in forward resistance and loss of effectiveness. All of these failures were discovered by operating personnel who observed the larger and more intense arc and the sharper noise when the contactors opened. The rectifier must be connected to the circuit with correct polarity and a fuse to isolate it in case of failure is recommended.

Figure 13. Oscillogram of discharge transient of closing coil suppressed by teaser electrode

Figure 14. Oscillogram of discharge transient of closing coil unsuppressed

Parallel Resistor

One of the oldest and best known means of discharge voltage suppression consists of paralleling the coil with a suitable resistor as shown in Figure 10. The solid arrows show current direction in the different branches with contactor closed and the broken arrows after the contactor has opened. Assuming arcless opening of the contactor and letting r_1 be the ohmic resistance of the coil, r_2 the resistance of the paralleling resistor, E_B the voltage of the control battery, and E_C the initial voltage across the coil, the steady state coil current is

$$I_1 = E_B/r_1$$

With all of this current transferred to the resistor at the instant the battery circuit is broken, the voltage across the coil and resistor in parallel is

$$E_c = I_1 r_2 \text{ or}$$

$$= E_B r_2/r_1 \qquad (5)$$

From this relation, it is evident that to limit the discharge voltage to a satisfactory value, the resistor must be low enough to draw an appreciable current while the coil is energized. When used with solenoids which are operated from a control battery, the additional current increases the battery duty and the voltage drop in both the battery and the connecting wires. With larger circuit breakers operating at higher speeds and with higher system short circuit currents, the maintaining of satisfactory voltage regulation at the solenoid is becoming increasingly difficult and care should be exercised in applying any device adversely affecting it. The method has proved entirely satisfactory when used with 250-volt closing coils which are supplied from a high-capacity source. It cannot be used with coils which require continuous monitoring.

Figure 15. Protective rectifier applied to control bus to limit discharge voltage transient after initial breakdown

Silicon Carbide Resistor

This method consists of paralleling the closing coil with a resistor whose resistance element is made of silicon carbide which has the well-known lightning arrester characteristic. Suppose a resistor having the characteristic

$$e = 100 \cdot i^{0.38}$$

is used to limit the discharge voltage of a coil having 0.5-ohms resistance and energized at 115 volts. The current drawn by the resistor at 115 volts is

$$= \left(\frac{E}{100}\right)^{\frac{1}{0.38}}$$

$$= 1.65 \text{ amperes}$$

The current through the closing coil at 115 volts is 115/0.5 = 230 amperes. Assuming that the contactor gives arcless performance and that the entire current is transferred to the discharge resistor, the discharge voltage will be

$$e = 100 \cdot 230^{0.38}$$

$$= 460 \text{ volts}$$

This example demonstrates the superiority of a material having a nonlinear characteristic over the conventional resistor. It does not consume sufficient current during the closing period to materially affect the voltage regulation at the solenoid and it does hold the discharge voltage within reasonable limits. Its use does not preclude continuous monitoring by conventional schemes, however, some modification may be necessary. Its characteristic is nondirectional which somewhat simplifies the installation. Units for this service are available and are furnished with some of the larger circuit breaker closing solenoids.

Teaser Contact

The so-called "teaser contact" consists of an electrode so located that it will be in the arc path as soon as the contacts separate and connected to the other side of the closing coil as shown in Figure 12. This method has given satisfactory service for several years with a few types of contactors. The location of the teaser electrode is critical as it must be in the arc path and near the stationary contact to ignite promptly and to hold the surge to a suitable value. It is applied most readily to a contactor having two series breaks. By removing the blowout coil and locating the additional electrode in the pole which is connected to the solenoid, the surge voltage is held to a consistently low value. The other break with its blowout coil quickly interrupts the current from the battery and precludes any possibility of a battery short circuit. A special study is required to tailor the arrangement to each type of contactor and rapid erosion of the arc chute may result from the impingement of the discharge arc. Too, with single-pole contactors there is always the possibility of a battery short circuit caused by failure to extinguish the arc between the teaser electrode and the moving contact. A fuse, selective with the main control fuse, is recommended so that in the event of a battery short circuit, the main fuse will not blow, leaving a closed circuit breaker without available tripping power.

Methods Applicable to Relays

The energy which can be stored in the magnetic fields of relays and its potentiality of damaging equipment or injuring personnel is very small when compared with that of circuit breaker closing solenoids and other large magnets. The very high discharge voltage of some relays is explained by equation 3 which shows the voltage to be proportional to the square of the number of turns, and by the fact that many relays have laminated iron structures. Despite the high voltages encountered, the authors have experienced a surprisingly small amount of trouble which could be traced directly to this source. It is very probable that the high voltage has damaged insulation but that the energy has been insufficient to effect a complete breakdown. Such damaged insulation may be broken down by subsequent periodic high-voltage tests. In general the same methods which are effective for the larger devices can be successfully applied with relays. With specific reference to the first method suggested for relays and which works very well, tests made on large devices with a contactor which had been slowed up mechanically and had its blowout coil removed showed only a moderate discharge voltage. However, the long duration of the arc increased the erosion of both contacts and arc chute sufficiently to render the method impractical where large energies are enountered. The following are particularly suitable for relays:

1. Use of a slower breaking switch or relay to open the coil circuit. This is permissible because energy is low.
2. Parallel the coil with a suitable resistor.
3. Parallel the coil or the interrupting contacts with a suitable condenser. (One to four microfarads should be sufficient and a low ohmic resistance may be put in series with it.)
4. Where justified, a dry-plate rectifier or a cold cathode gaseous discharge rectifier

similar to the type *OZ-4* affords excellent surge protection for small relays.

Protective Rectifier Applied to a Control Bus

There is one other method that, while it is not used to suppress discharge voltages directly, is so closely allied to the whole problem that it should be described here. It consists of a half-wave or blocking rectifier connected across the battery with its mid-point grounded as shown in Figure 15. Each half of the rectifier selected for this application should be capable of withstanding full battery potential in the blocking direction and of discharging the largest solenoid in the station several times in rapid succession. It should have a high reverse resistance as any current drawn by the rectifier raises its temperature and of secondary importance increases the battery load. Its resistance should be stable because unbalance between the two halves affects the functioning of the ground detector lamps.

A rectifier so applied, does not normally limit or control the discharge voltage nor does it decrease the contactor duty as do most other methods. It does provide at all times a low-resistance high-capacity path to limit the voltage between the battery and ground, should a failure to ground occur due to discharge of any inductive device connected to the battery. In the event of a failure to ground, as indicated in Figure 15, the discharge current flows from the coil, through the rectifier to ground, and returns to the coil through the insulation failure; thus affording a low-resistance discharge circuit and holding the battery-to-ground voltage to a safe value. Most of the danger to personnel, service, and equipment which arises from discharge voltages is caused by imposing a high voltage, backed up by considerable energy, between the station control and ground. By reducing this danger to a minimum, a rectifier connected from battery to ground accomplishes most of the important functions of any of the other methods which must be applied to each inductive device. Its chief virtue is that but one per station is required and that it can be put in operation with a minimum of time, labor, and material. Its limitation is that high voltage and possible breakdown at the danger point between the coil in question and the de-energizing contacts are not prevented, but their effects are minimized.

A — Transient volage not suppressed
B — Transient voltage suppressed by discharge rectifier

Conclusions

1. There is a high voltage produced by the decay of flux when an inductive device is de-energized. Uncontrolled, it may injure personnel, interrupt service, and damage equipment.

2. The magnitude of this voltage depends on the value of the energizing voltage, the size, shape, and material of the magnetic circuit, the number of coil turns, and the speed of de-energizing. The discharge voltage of a small relay is often higher than that of a large circuit breaker closing solenoid.

3. The energy stored in the inductive circuit varies approximately with the size of the device.

4. A dry-plate rectifier paralleling the coil of each inductive device holds the discharge voltage to a safe value. A slow acting switch, a small capacitor (1 to 4 microfarads), a small resistor, or a gaseous discharge rectifier performs well when used with small low-energy devices such as control relays.

5. A dry-plate rectifier connected across the control battery with its mid-point grounded prevents the communication of high discharge voltage between circuits.

6. All these methods of reducing the surge voltage involve slowing the transfer of stored magnetic energy to the electric circuit, which in turn delays the dropout of relays or solenoids. This delay is usually not objectionable but must be evaluated carefully.

Discussion

J. H. Kinghorn (American Gas and Electric Service Corporation, New York, N. Y.): Halman and Harris have presented a clear picture of the conditions which can produce high transient voltage on control circuits and the conventional methods of limiting this voltage. They indicate that while such voltages can be produced by de-energizing any type of inductive device, it is circuit breaker closing solenoids which are the principal causes of subsequent damage to other parts of the control system because of the greater amount of stored energy involved. This agrees closely with experience on the system with which the writer is associated. In the few cases of insulation failure which could be attributed to high induced relay coil voltage the damage was confined to the insulation of the coil itself, and did not produce further breakdown elsewhere in control circuit.

The methods of voltage suppression described all depend for their effectiveness on providing a discharge path for the coil current. This means additional equipment in the form of discharge contacts, resistors, or rectifiers, all of which are subject to failure which can easily go undetected. It would appear that a more direct approach might be to limit the possible induced voltage by the design of the device or to provide sufficient insulation strength in the coil and associated contactor connection to prevent breakdown. The latter may be an unreason-

able approach, particularly since this insulation is sometimes subject to exposure to moisture. The former, however, implies some means of delaying flux collapse by suitable design. The authors point out that magnetic circuit design which will delay flux collapse also usually delays flux buildup and consequently increases to some extent the pickup time. It would be helpful if some figures could be presented showing the relative magnitude of these effects. Perhaps sufficient modification of design could be tolerated to limit induced voltages to a value which would require only a moderate increase in insulation strength to assure trouble-free operation. This same line of reasoning can be applied to relays, except that in this case there are some applications where no delay in pickup time is acceptable and any method of delaying flux decay must not increase it. Again, however, an increase in relay-coil insulation strength combined with magnetic circuit revision may offer a practical solution.

J. Russell Taylor (Igranic Electric Company, Ltd., Bedford, England): As co-author of the first paper mentioned in the references, I am most interested in the investigations of Halman and Harris.

Randall and I studied the surges caused by contactor coils, and our tests showed that the general tendency was towards an increase of surge voltage with increase of contactor size. For any given coil the maximum voltage surge always corresponds with an optimum capacity across the coil.

The present authors state that the amount of capacity across the coil has no effect on the maximum surge voltage, but merely on the shape of the tail. Our investigation with contactor coils on 230-volt direct current having resistances varying between 2,000 ohms and 400 ohms fitted to contactors of 150 amperes to 1,200 amperes, showed conclusively that there is a sharply defined optimum capacity for each size of coil which gives the highest surge voltage. With capacities smaller than the optimum there is a fairly rapid drop in the surge voltage, but with capacities larger than the optimum, the lowering of the surge voltage is much more gradual.

Possibly the discrepancy lies in the greater power dissipation of the circuit breaker closing coils mentioned in the present paper than with continuously rated contactor coils. It may be that the former coils with their heavy current alter the effect of the arc at the switch contacts.

In view of the very large voltages produced across the contactor or solenoid coil it is indeed surprising that coil and insulation failures are not much more common than they are.

Have the authors evolved any means of predetermining the surge voltage from the dimensions of the coil and the magnetic circuit?

V. J. Hayes (Connecticut Light and Power Company, Waterbury, Conn.): This interesting paper by Halman and Harris is of importance not only to relay engineers but to those who are concerned with maintenance in stations that employ d-c control systems. The statement in this paper that the discharge of small relay coils can produce surge voltages from two to three times those of the larger solenoids should be of particular interest; because some stations (such as generating plants) may use a considerable number of such relays in control of auxiliary equipment, and these devices are usually subject to more frequent operation than are large circuit breakers. Since it may not appear practical or economically justifiable in such cases to add shunt resistors or dry-plate rectifiers to each of these relay coil circuits, the use of the one protective rectifier applied to a control bus becomes attractive, as described under the heading Protective Rectifier Applied to a Control Bus in the paper.

The use of the shunt resistor (suitably protected by a fuse) across circuit breaker trip coils is of interest not only for its d-c surge voltage limiting feature, but because the current drawn by this resistor when the trip coil is energized reaches its full value almost instantly. This characteristic is often helpful in obtaining faster and more positive operation of seal-in contactors and devices in tripping relays, which otherwise would normally have to depend upon the relatively slower buildup time of the current in the trip coil proper.

E. L. Michelson (Commonwealth Edison Company, Chicago, Ill.): This paper by Halman and Harris is an excellent contribution to the literature on voltage surges in control circuits. Their paper gives a very clear picture of the initiation of these surges, the manner in which they may cause troubles of various kinds, and the possible methods of designing the circuits in such a way as to minimize the effects of transient voltages.

The AIEE relay committee recently set up a project committee to study the insulation of relay control circuits. This paper was initiated through the efforts of the project committee, and will be a valuable part of the work of this project committee. The project committee has been attempting to work out a reasonable co-ordination between the maximum permissible voltage in the control circuits and the design of relays, circuit breaker controls, and other items that make up the control circuits. At the present time, it appears that satisfactory operation will be obtained if the maximum transient voltage in the control circuits is limited to 1,500 volts crest value. This will result in co-ordination between the circuit breaker control wiring standards and the permissible relay test voltages. The Association of Edison Illuminating Companies (AEIC) specifications for oil circuit breakers specify that the inductive kick caused by interrupting closing currents shall be less than 1,500 volts crest. The AIEE relay standard, which is now being reviewed, will recommend a test voltage for relay circuits of 1,125 volts rms.

There have been a few instances where voltage surges in control circuits have been caused by other phenonena besides the inductive kick of relay and circuit breaker coils. One case with which I am familiar was caused by the capacitive coupling between the 66-kv cables and the control wiring of a relay circuit. Sudden application of voltage to the high-voltage cables caused sufficient transient voltage to flash over the contacts of a protective relay and cause a transmission line to be opened. In this case the condition was corrected by the installation of capacitors in the control circuit.

J. A. Elzi (Commonwealth and Southern Corporation, Jackson, Mich.): The phenomenon so well described and analyzed in this paper is one which many of us may have encountered in the past but which has not in general been given due recognition. The AEIC specifications for alternating current power circuit breakers takes cognizance of the voltage induced by circuit breaker solenoids and specifies that: "The transient voltage due to the interruption of the control current shall be limited to 1,500 volts crest." This we understand is about the practical limit and it is noted that the authors have measured transient voltages of 1,700 volts for 125-volt solenoids and 2,500 volts for 250-volt solenoids.

From the work now being engaged in by the relay committee it appears that it may be found difficult to provide relays having a withstand test voltage in excess of 1,500 volts rms 60 cycles for one minute when new. The recommended test voltage for field tests will probably be somewhat below this.

These facts strongly indicate the necessity of co-ordination between the dielectric strength of control circuits and devices and the transient voltage to which they are subjected. Considering the practical limitations involved, it seems most logical to provide means in the control circuits or devices such as the authors have described to reduce the transient voltages.

Several cases of incorrect relay operation due to high induced voltage are mentioned in this paper. We strongly suspect that others of us may have had similar incorrect operations without recognizing their true cause.

This phenomenon is not confined to control circuits. We recall an instance in which trouble was experienced due to flashover of the rheostat shunting contactors of a voltage regulator in a quick response excitation system. In this case there were two contactors each short circuiting a block of resistance in the main exciter field circuit. The transient voltage across each contactor when it opened was found to be 2,100 volts. In these larger contactors it was practicable to provide adequate insulation to withstand this voltage, but repeated stresses of this magnitude may be conducive to ultimate failure and a means of reducing them is highly desirable.

Tony Offenbacker (Indianapolis Power and Light Company, Indianapolis, Ind.): The investigation of the false relaying that occurred on pilot wire relays that have contact separation of 0.01 inch or less indicated definitely that overvoltage surges or transients were causing the contact breakdown. These conditions took place on a control system that had no unintentional circuit grounds. The discussion in the paper seemed to indicate that no overvoltages occurred on this type circuit arrangement.

The type of measuring equipment has a great bearing on the results obtained. Using the magnetic oscillograph, no overvoltages or transients could be detected, but by using the trigger action of a gas tube, many operations resulted. The cathode ray oscilloscope will show quite a lot of oscillations

and pulsations when placed across a battery during various current carrying circuit interruptions. Probably a very sensitive transient recorder would show more.

When experimenting with interrupting current carrying circuits using the trigger action of the gas tube as a measuring device, it was very noticeable that operation of the gas tube did not depend so much on the type circuit interrupted as it was on how much an arc the interruption caused. The circuit interruption of an ordinary light, if done slowly to cause arcing, would set off the gas tube. Of course, any inductive circuit would tend to arc with greater intensity to create more disturbance.

If an arc sets up a disturbance composed of many frequencies because of the distributed capacity of the inductive coils and the inductance of these coils, some one frequency may be of such value so as to set up an oscillatory condition. This condition gives rise to a localized high voltage either high or low frequency. A potential of high enough value may be obtained to cause breakdown of the relay contacts. The follow-up power flow would then complete the equipment operation.

If the theory that high frequencies are set up in the various circuits due to arcing is true, ways and means of measuring and controlling them must be found. The methods of surge voltage control suggested in the paper may not be satisfactory. Even the use of a capacitor across the battery should be made with caution to prevent making the condition worse.

Since most relay contacts have a separation in excess of 0.01 inch, not much trouble is to be expected with the present type relays. On the other hand many relay schemes are being advanced using electronic equipment with their small contactors and close contact separation so the problem may become more serious in the future.

Lacking the necessary sensitive measuring and recording instruments, the foregoing theory cannot be definitely proved, but it seems there is some other condition taking place than the inductive surge.

T. R. Halman and L. K. Harris: The discussion on this paper is greatly appreciated and leads us to believe that the subject is of general interest and that the experiences, troubles, and even the thinking of other operators closely parallel our own. The incident depicted by Michelson shows that not all high-voltage surges on control circuits originate with devices electrically connected to them. It is surprising that there is sufficient electrostatic coupling between the 66-kv cables and the control wiring to induce a voltage capable of breaking down relay contacts, even when special grounding methods are used to reduce sheath losses.

We have had little experience with high speed excitation and have not encountered trouble similar to that described by Elzi. It appears to be a case where increasing insulation and dielectric strength is the only feasible solution. We have considered the use of suppressors to protect synchronous capacitor field windings when the field circuit breaker is suddenly opened. No applications have been made.

We were very pleased to receive Taylor's comments since he and Randall had made a thorough study and published a comprehensive paper on a different phase of the same subject. While the premise of an optimum capacity for each device was not worked out completely in our paper, it was accepted and some readings were obtained to verify it. Our statement that the amount of capacity across the coil has no material effect on the maximum surge voltage was limited to 125-volt closing solenoids having coil resistances between one-half and $1^1/_4$ ohms and connected to control busses involving total capacitances ranging from 0.05 to 6.0 microfarads. These capacitances were much below the optimum values for the respective coils. We have not evolved a method of determining the magnitude of the surge voltage from physical dimensions of the coil and magnetic circuit. Such a relation, if worked out, would include the speed of current interruption, that is, the type of control contactor. Modern solenoids, using cast steel or fabricated steel plate for their magnetic circuits, show appreciably lower discharge voltages than earlier ones which used cast iron. The decrease can be very largely attributed to the lower resistivity of the steel.

The use of a resistor, suitably fused, in parallel with the trip coil of a circuit breaker, as suggested by Hayes, is one of those rare applications where one piece of equipment gives two independent beneficial effects. We have experienced some minor difficulties with this seal-in problem when using lockout relays in series with trip coils. They have been overcome by selecting relays with low pick up values and with shorter time constants than the associated trip coils. We have not used the paralleling resistor because it would impair the significance of our standard trip coil circuit monitoring.

Kinghorn's experience with relays supports our contention that while very high surge voltages may be produced in relay coils, should an insulation breakdown occur, the surge is effectively suppressed by the battery grounding lamps and the capacitance to ground of the control wiring. Regarding reliability and detection of failures, our experience, covering about ten years indicates that a rectifier possesses a high degree of reliability in this service. Also with periodic inspection and maintenance there is small probability that a failure will be long undetected.

We believe that the AEIC specifications, which limit the transient discharge voltage to less than 1,500 volts crest, have established a value about as low as it is feasible to meet by practical design. This value will be altered by the type of control contactor used (speed of current interruption); a factor often not under the control of the designer. Increasing coil insulation to withstand higher voltage would logically result in larger and more expensive solenoid mechanisms. It could not be applied to existing solenoids and they will continue to be serviceable for many years. As Michelson points out, the AIEE relay standard will recommend a test voltage of 1,125 volts rms for relay circuits. This corresponds to about 1,600-volts crest. It will be applied at relatively long intervals, from a low-power source, to equipment which has been removed from service, and at a time when facilities are available to repair possible damage. We believe that such a test voltage should be much higher than a voltage caused by the normal functioning of equipment and which has sufficient energy to do serious damage.

Offenbacker's discussion outlines an interesting problem of high frequency oscillations on a tripping bus which cannot be summarily dismissed. He offers an ingenious method of determining the peak value of high-frequency low-energy surges and the capacitor which he uses affords a practical means of suppression. We are somewhat at a loss to know why we have not encountered similar troubles. There are two plausible explanations which occur to us. We are using high-speed relays with close contact spacing only in large stations where the capacitance to ground exceeds 1 microfarad. This capacitance may be effective in suppressing the high-frequency surges. Also we connect each trip circuit directly across the main control bus instead of using a tripping bus.

If the tripping bus has very low capacitance, as seems probable, a low-energy transient may cause a high-frequency high-voltage oscillation. We were not able to trip a gas-tube relay set a few volts above battery voltage even by interrupting the field of a 50-kva alternator or the coil of a circuit breaker closing solenoid. Similar operations showed a moderate-frequency transient with a crest value not exceeding 15 volts when viewed on a 5-inch oscilloscope having an input impedance of 2 megohms.

Electronic Protective Relays

IN THEIR PRESENT state of development, electromagnetic protective relays possess characteristics and reliability well abreast of the demands of power system protection. However, the attainment of this status has been fraught with many problems for which ideal solutions have not been found. Further development in system design, such as high-speed reclosing, together with the increasing demand for higher degrees of accuracy, speed, and dependability, have accentuated these problems to a point where the inherent limitations of electromagnetic relays are raising barriers to the achievement of desired goals.

The increasing use of electronic circuits in nearly all branches of electrical engineering, coupled with the great strides that have been made recently in the design and manufacture of electronic circuit components, seem to point the way to the use of electronic means for lifting these barriers.

In view of the widespread interest in electronic devices of all kinds, it is not surprising that protection engineers have developed a keen interest in electronic protective relays. This interest, however, has not resulted in general enthusiasm for such relays because many relay engineers are thoroughly satisfied with electromagnetic relays. On the other hand, some operators would welcome a complete line of electronic relays. Some of the latter group have been inclined to attribute the lack of electronic relays to, what is to them, a reactionary attitude. This paper is intended to present both a report of progress, and an explanation of the present limited availability of such relays.

The limited number of electronic relays should not be assumed to indicate any serious lack of interest or ingenuity. To the relay engineer, electronic circuits are merely one of the many tools available for obtaining the characteristics necessary for discrimination between normal and abnormal conditions in a power system. Typical of such tools that have been available to relay engineers for many years are nonlinear resistors, rectifiers, and neon lamps.

Early Work

The following examples show that electronic relays are by no means new, and that manufacturers have been aware of their potentialities ever since practical tubes were available.

In 1927, A. S. Fitzgerald developed an electronic pilot relay system[1] (Figure 1) to overcome the limitations of pilot wires when operating over considerable distances. This scheme was abandoned because of the short life and the high cost of tubes available at that time, but a somewhat similar scheme is now in active use as the phase-comparison relay[2] (Figure 2). Fitzgerald's was the first well-known application of electronic protective relays.

In 1931, Rolf Wideröe of Norway developed electronic circuits for most of the common types of protective relays and described them in a paper presented before the Institute in 1934.[3]

In 1932, in the United States, a laboratory sample electronic reactance relay[4] was built and tested, but at that time the electromagnetic reactance relay was fully adequate for the needs of the industry and no steps were taken to put the electronic relay into production. This type of electronic relay was built because it embodied all the common relay principles in a single relay and hence presented all the problems of the different types, such as over-current, undervoltage, directional, phase angle, and differential relays. In other words, the reactance relay was a good guinea pig. The experience gained from this development was destined to become valuable for future developments.

Directional-comparison carrier-pilot relaying, using electromagnetic directional relays to discriminate (by their joint action) between internal and external faults[5,6] (Figure 3), came out in 1930. This type was extended in 1936[7,8] to include the back-up function in the form of distance relays (Figure 4). Neither of these can be classed as an electronic relay, because the discriminating relays are electromagnetic and the electronic circuit is limited to transmitting and receiving signals along the transmission line; i.e., only the communicating channel is electronic. On the other hand, this application has been so successful and widespread that it is valuable as a source of information on the life and behavior of electronic components such as tubes, tube sockets, and small resistors.

An electronic synchronizing relay (Figure 5) was built in 1934 and has been used widely ever since. This was a case where the use of an electronic device was justified because it could achieve results not economically obtainable with an electromagnetic relay.

In 1936, an electronic timing meter (Figure 6) was designed for testing high-speed relays. It measured down to one millisecond, and hence was very much better than existing synchronous timers, and was considerably more convenient to use than an oscillograph.

Since then there have been a number of miscellaneous electronic applications

Paper 48-310, recommended by the AIEE relay and electronics committees and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, October 18-22, 1948. Manuscript submitted August 3, 1948; made available for printing September 15, 1948.

R. H. MACPHERSON and A. R. VAN C. WARRINGTON are with the relay engineering, switchgear division, General Electric Company, Philadelphia, Pa.; and A. J. McCONNELL is with the central station engineering divisions of the General Electric Company, Schenectady, N. Y.

Figure 1. Early electronic pilot relay for carrier-current application

Figure 2. Phase comparison pilot relay

to relays, mostly in connection with the war effort; but, in general during the last ten years, there have been few cases where it was felt that an electronic relay would do the job better than an electromagnetic relay.

Carrier Relaying

Carrier relaying is the principal source of experience with tubes. In the early days of carrier relaying, tubes had a very irregular life and required frequent replacement. This led to the general specification that the tripping of a circuit breaker should not depend upon the proper operation of a tube.

Tubes have improved gradually, so that today the average replacement does not exceed once a year. Improvement in tubes has reduced skepticism to the point where tripping via tubes is considered acceptable. This is shown by the fact that available forms of phase- or current-comparison relaying require tube operation for the tripping function.

Why has carrier-current relaying attained such widespread use, whereas other types of electronic relays are few? The major reason is undoubtedly that carrier relaying has accomplished a highly desirable result not economically feasible by any other known method. This popularity is in spite of known limitations of electronic circuits. In other words, the outstanding advantages of carrier relaying outweigh its minor disadvantages.

Requirements for Electronic Relay

If an electronic relay is to compete with an existing electromagnetic device, it must offer advantages, not just novelty. This is particularly evident when the wealth of experience available on electromagnetic relays is considered.

The most desirable improvements over existing relays are in speed, burdens, maintenance, reliability, accuracy, and reduction of the number of contacts. At the present time it is evident that low burdens can be expected with electronic relays and that the operating time can be around one cycle and consistent, being the same at pickup as at many times pickup. This characteristic alone may justify the use of tubes in the protection of transmission lines with ultrahigh-speed reclosing.

The cost of electronic relays depends on their complexity. A simple relay, such as a time overcurrent relay, would be much more expensive than the magnetic version. However, a complex relay such as a synchronizing relay or a distance relay, may be comparable in cost.

Skepticism with respect to electronic relays is based largely on the contention that radio components are not equal to those normally used in relays. Capacitors and resistors present no problem because the standard relay types can be used. This leaves the tubes and tube sockets. The advent of the new long-life tubes may be the answer to the problem of tube life, but this can be found out only by some years of experience. Tube sockets are available with good contact pressure which would appear satisfactory, but here again a period of experience may be necessary.

In any electronic relay circuit, it is essential that the characteristics of the tube should not control the relay characteristics, otherwise the aging of the tube may change the relay characteristics. However, if the characteristic can be restored by a simple adjustment, which can be readily checked by a simple test, then this requirement may be waived. In other words, if a change of a few per cent in pickup occurs in a period of a year, or when a tube is replaced, and it can be restored by a simple adjustment, this condition may be considered satisfactory.

The effect of transients is an important factor because the operation of an electronic relay depends upon the comparison of instantaneous values of current and potential.

The battery drain should be small, if

continuous. Normal variations in battery voltage should not interfere appreciably with the characteristics of the device.

The circuits and their controls should not be so complicated that the ordinary relay test man has to be replaced by a radio engineer.

The Present Outlook

Two things have tended recently to increase the interest in electronic relays: the advent of long-life tubes; and the necessity for consistent low operating times, even at low currents, for more effective use of instantaneous reclosing.

Long-life tubes have been developed by tube manufacturers in a few forms such as a pentode, a high-mu twin triode, and a low-mu twin triode, all of which are useful in relay circuits.

In reclosing after a fault it is essential that both ends of the section trip within a few cycles of the same time. The inertia of electromagnetic relays tends to make the relays at the end remote from the fault operate more slowly than those at the end near the fault, especially during minimum generating conditions. An electronic tube has no inertia, so that it is possible to design the circuit so that relay operating time is not affected by current magnitude or fault location; consequently both ends of the section can be cleared simultaneously.

While these improvements in components and this need for high-speed operation seem to have pointed to the desirability of electronic protective relays, it is not proposed to introduce such relays without first accumulating some practical experience with them.

While electronic relays now can be built to perform nearly any protective function, the question of whether they can do a better job, all things considered, depends upon the application. For instance, the single unit induction cylinder polyphase directional relay is a compact efficient device occupying about the space of a 4-inch cube. The corresponding electronic relay would involve at least a 6-tube circuit of considerable complexity and, with presently available components, would occupy more space and be more costly. Again, the induction time overcurrent relay sets a standard of simplicity and reliability that would be difficult to meet with an electronic circuit. Finally it is doubtful if any electronic means could effectively take the place of any of the more common auxiliary relays.

In short, the electronic relay is a valuable tool which has been long appreciated and which has been used wherever it could do a better job than an electromagnetic relay. As improvements are made in the tubes and their accessories, their use will increase and they will certainly be used for new applications where the existing relays are inadequate.

The Electronic Mho Relay

To evaluate accurately the relative merits of the electromagnetic and electronic relays, it was decided to build a sample 3-zone electronic mho relay and to compare its characteristics with those of an electromagnetic mho relay. The results were sufficiently encouraging to

Figure 3. Directional comparison carrier pilot relay

Figure 4. Distance carrier pilot relaying equipment

Figure 5. Electronic synchronizing relay

Figure 6. Electronic timing meter

warrant building a three-phase terminal which could be put in service on an actual transmission line for a period of operation which would include a lightning season. The selection of the mho relay was based on reasons previously discussed in connection with an early electronic reactance relay, that is, it combines almost all the principles now used in protective relaying. Successful development of the mho relay would imply that little difficulty would be experienced in building some of the simpler high-speed relays.

Description and Operation

One way to build a relay with a mho characteristic is to compare line voltage with line current at the moment of the line-voltage maximum. A typical unit would consist of three basic elements: a pulsing circuit, a measuring circuit, and a tube circuit. This arrangement is shown in block diagram form in Figure 10.

The function of the pulsing circuit is to generate a pulse at the moment of line-voltage maximum. The pulse is used to overcome a large grid bias and permit a tube to conduct. The function of the measuring circuit is to compare the line voltage with the line current. It consists of a transformer supplied with line-to-line voltage and a transactor (defined later) supplied with the corresponding line currents. The secondary of the transactor is provided with a voltage divider which makes possible different impedance pick-up settings. An adjustable phase-shifting circuit also is provided to allow the point of maximum reach on the mho characteristic (Figure 11) to occur at different angles.

Figure 7. Thyratron pilot wire relay

The tube circuit is the sensitive element which is responsive to signals from both the measuring circuit and the pulsing circuit. The tube circuit also initiates the tripping signal to the circuit breaker when the impedance being measured falls below that for which the relay has been set to operate.

Figure 12 shows graphically the line voltage V, the line current I, and related quantities as applied to a typical unit during fault conditions. The pulse (V_p) as generated by the pulsing circuit is seen to occur at the moment of line voltage maximum. The line current (I) is passed through the primary of the transactor in the measuring circuit. A transactor is an air-gap transformer and has a secondary voltage proportional to the primary current. Normally, this secondary voltage leads the primary current by 90 degrees. Actually, it is desirable that this angle be made adjustable by means of a phase-shifting circuit. The dotted wave in Figure 12 represents the shifted secondary transactor voltage. The polarity of the transactor is reversed so that the direction of its secondary voltage will be opposite to that of the line voltage.

In the measuring circuit the line voltage (V) and the voltage proportional to the line current (V_I) are opposed and the combination placed on the grid of a tube in the tube circuit. The direction of the voltage is such that it tends to hold the tube off at the measuring moment (instant of line-voltage maximum) while the direction of the voltage proportional to the line current is such that it tends to cause the tube to conduct at the measuring moment. The line voltage could be considered to have a restraining effect, while the current has an operating effect. A bias in this series circuit is adjusted so that at the measuring moment the tube will conduct when the voltage proportional to the line current just equals the line voltage.

In the Appendix, it is shown mathematically that the arrangement described will have a mho-type operating characteristic. It also should be pointed out that, to build a unit with a reactance characteristic (Figure 13), similar basic elements are used, that is, a pulsing circuit, a measuring circuit, and a tube circuit. The difference is that the measuring moment occurs at the time of the line-current zero. This is also shown mathematically in Appendix A.

Figure 8. Sample electronic mho relay

Referring again to Figure 12, it can be seen that the current will have its greatest effect when the power-factor angle is equal to the angle between the voltage V_I and the line current I since for this condition V_I is a maximum at the measuring moment. This angle then is the angle of maximum reach on the mho characteristic.

Operating Time

Owing to inertia, measurements made by electromagnetic relays must be made on a rms basis. In electronic relays, on the other hand, no inertia is present and

Figure 9 (left). Sample electronic timing relay

Figure 11 (right). Mho characteristic on R-X diagram

measurements may be made on an instantaneous basis. The use of instantaneous values for measurement makes the electronic relay inherently faster in operating time. The electromagnetic relay must integrate the quantities being compared over a period of time before it can determine the magnitude of the quantity being measured.

As the electronic mho relay compares instantaneous values of voltage and current only at the moment of the line-voltage maximum, the operating time will depend on the moment in the cycle the fault occurs. This may be understood by considering a fault which occurs at some time after the line voltage maximum. The relay must wait until the next line voltage maximum occurs before measurement can be made. If only a single tube is used, the operating time will vary from 0 to 1 cycle plus the operating time of an auxiliary tripping relay. On the other hand, the use of two tubes reduces the operating time from 0 to 1/2 cycle plus the operating time of an auxiliary tripping relay. One tube would be made conductive at the moment of positive half cycle line voltage maximum and the other at the moment of the negative half cycle line voltage maximum. Each would have the proper signal from the measuring circuit on its control grid. The operating time is independent of the impedance the relay sees, expressed as a percentage of the pickup setting. This is illustrated in Figure 14.

Burdens

As can be expected with electronic devices, the burdens of the electronic mho relay are very low. Each current circuit burden is less than 2.5 volt-amperes at 5 amperes, and the potential circuit burden is less than 1.5 volt-amperes at 115 volts.

Effect of Transients

Transient shunts are provided to eliminate the d-c component of the fault current wave. Unless the transient shunt is used there is a tendency for the relay to overreach owing to the instantaneous nature of the measurements. When a single tube is used without the transient shunt and a fault occurs near the end of the protected section during the positive half cycle of the line voltage, there will be negative offset and tripping will be delayed until the offset portion of the current has decayed.

An Electronic Timing Relay

The two time steps required for the 3-zone electronic mho relay are furnished by an external electronic timing unit. These time steps are independently adjustable over a range of 0.05 to 3.5 seconds.

The time delay is obtained by means of the well-known RC decay circuit; a capacitor in the grid circuit of a tube normally is charged negatively to a certain fraction of the d-c supply voltage by means of a potentiometer connected across the d-c supply. This setting controls the operating time because the capacitor discharges through a resistor until it reaches the point where its negative voltage is reduced sufficiently to permit the tube to fire.

An important feature of this timing unit is that, unlike most devices using an *RC* timing circuit, its connections are such as to make the operating time practically independent of the variation of the d-c supply voltage.

Conclusions

Before electronic relays can be accepted in the protective relay field, they must be at least as good as electromagnetic relays in all respects and superior from the standpoint of one or more of the following: reliability, speed, accuracy, burden, and maintenance. Their application also is justified where they can be made to perform functions not possible, or not economically feasible, with electromagnetic relays.

It has been found possible to build a typical high-accuracy electronic protective relay which, laboratory tests indicate, is in every way as good as its electromagnetic counterpart, and in addition, provides faster and more consistent operating time, greater sensitivity, and lower burden. Laboratory tests, however, cannot be considered as the final measure of performance in actual service. Accordingly, plans for comprehensive operating tests on a power system currently are being carried out and, if these tests prove successful, the relay will be made available for applications where its superior speed, sensitivity, and burden

Figure 12. Currents and voltages applied to mho unit

Figure 10. Block diagram showing arrangement of electronic distance relays

Figure 13. Reactance characteristic on R-X diagram

Figure 14. Time characteristics of electromagnetic and electronic relays

characteristics are considered advantageous.

In the meantime, development work will continue in order to explore the further possibilities of electronic relays so that when there are applications requiring features which can be obtained better with electronic relays than with electromagnetic relays, the industry will find that they will be available.

Appendix

The operation of the electronic mho relay may be considered mathematically as follows.

Expressions for instantaneous values of the quantities to be compared are

$$e = E_{max} \sin wt \tag{1}$$

and

$$i = I_{max} \sin (wt + \phi) \tag{2}$$

where e is the instantaneous value of line voltage, E_{max} is the peak value of line voltage, i is the instantaneous value of line current, I_{max} is the peak value of line current, ϕ is the power factor angle, wt is the angular velocity in radians per second of the alternating current, and t is the time in seconds from a zero point on the voltage wave. In the relay the current is further shifted by an angle θ and both current and voltage are modified by constants K' and K respectively. The bias on the control grid of the relay tube is such that it will conduct when the voltage proportional to the line current $[K'I_{max} \sin (wt+\phi-\theta)]$ just exceeds the line voltage as modified by the relay $(KE_{max} \sin wt)$, that is, the threshold value is given by

$$KE_{max} \sin wt = K'I_{max} \sin (wt+\phi-\theta) \tag{3}$$

Expanding the right-hand side of equation 3

$$KE_{max} \sin wt = K'I_{max} [\sin wt \cos (\phi-\theta) + \cos wt \sin (\phi-\theta)] \tag{4}$$

Considering the moment of the line voltage maximum where measuring is to take place,

$$wt = 90 \text{ degrees} \tag{5}$$

Substituting in equation 4,

$$KE_{max} = K'I \cos (\phi-\theta) \tag{6}$$

$$Z = \frac{K'}{K} \cos (\phi-\theta) \tag{7}$$

which is the polar equation of a mho circle with diameter equal to K'/K. (See Figure 11.)

It has been stated the relay described in this paper may be made to have a reactance characteristic by causing the measuring moment to occur at the instant of line current zero. To show that this arrangement produces a reactance characteristic consider equation 2. The line current will be zero when

$$wt + \phi = 0$$

or

$$wt = -\phi \tag{8}$$

and substituting in equation 3

$$-KE_{max} \sin \phi = -K'I_{max} \sin \theta \tag{9}$$

or

$$Z \sin \phi = \frac{K'}{K} \sin \theta = K'' \tag{10}$$

since θ is the relay angle and is constant.

Since $Z \sin \phi = X$,

$$X = K'' \tag{11}$$

which shows that a unit so arranged would have a pickup at a constant value of reactance.

Discussion

Archie W. Adams (Bonneville Power Administration, Portland, Ore.): The development work on electronic relays outlined in this paper appears to be an important step in obtaining higher speed relaying. In order to adequately handle load increases, it is necessary to raise the power capabilities of transmission lines. Modern oil circuit breakers are available to open in less than 3 cycles and with reclosing times of 20 cycles or less. In order to obtain the maximum advantage of these circuit breakers, relay operating times should be reduced to less than 1 cycle.

Stability studies on the Bonneville Power Administration system indicate a definite need for high speed and simultaneous operation of the relays at both ends of the line in order that we may utilize fast automatic reclosing of the circuit breakers.

We have recently made some preliminary tests on the deionization times for high-voltage arcs. These results appear to indicate that regardless of the magnitude of fault current the deionization time is less for short duration fault currents. From this standpoint, fast relaying is necessary in order to obtain faster reclosing times. This is in addition to the obvious advantage of reducing system shock by keeping the duration of fault current to a minimum value.

The Bonneville system has not been able to obtain satisfactory speed of relaying using the conventional distance-type relays. The principal reason for the present comparatively slow relay time is due to the low operating torques of the relay elements and an operating point for far end faults near the pickup value of the relay. The low operating torques are the result of fault currents from one end of the line that are of the same relative magnitude as load currents. In spite of the heavy faults on the Bonneville-Grand Coulee transmission system, the line lengths are such that, until the first circuit breaker has opened, the fault current from the far end of the line is small. We have found it necessary to set the carrier relay zone so that it extends not more than 15 or 20 per cent beyond the line section in order to minimize relay operations during system swings. This setting results in slow operating time for certain fault locations. An alternate solution would be to use "blinders" and extend the relay setting. Up to the present time, we have not applied these "blinders" because of the desire to keep our relaying as simple as possible.

The electronic mho relay outlined in this paper with high-speed operation up to the pickup setting of the relay should considerably shorten relay operating times which we have been able to obtain from conventional relays.

On the basis of our experience with present relays and our stability studies which show the improved system performance to be expected with faster relaying and high-speed reclosing, we believe that the manufacturers should expedite this type of relay development in order to produce the most reliable, simple, and fastest relay system possible.

C. E. Asbury (The Commonwealth and Southern Corporation, Jackson, Mich.): It is interesting to see further investigation and development work being carried on to

improve the reliability and performance of protective relaying. Because of the generally accepted use of carrier current relaying and the development of better electronic tubes, it appears to be timely that the possibilities for protective relay development in the field of electronics be explored further.

One of the limitations to the application of carrier current relaying is its complexity, not only from the standpoint of installation, but also from an operation and maintenance point of view. The present day cost of carrier current relaying also limits its application in many instances. Most of this cost is in the electronic equipment, coupling capacitors, and wave traps making up the carrier channel rather than the cost of the magnetic relays controlling this channel.

Since the component parts of electronic equipment such as tubes, condensers, resistors and sockets, have already been developed and are in mass production for other uses, it would appear that the manufacture of electronic relays could be reduced to an assembly process once a design is established and such products placed on the market at a much lower cost to the customer than the equivalent magnetic relay requiring special manufacturing processes for a number of special parts in rather small quantities.

In comparing electronic relays with magnetic relays not only should the reliability, speed, accuracy, burden, and maintenance, as mentioned by the authors, be considered, but also the cost, complexity, and space requirements should be considered. It would be interesting to know the space requirements for the new electronic mho relay as compared with that required for the magnetic mho relay.

One of the problems encountered with directional phase relays is the necessity of providing a voltage so that directional discrimination can be obtained during fault conditions when the voltage polarizing source may be quite low. In some relays this is done by using voltage insofar as possible from unfaulted phases. These arrangements are still subject to possible incorrect directional indication for close-in 3-phase faults. In the magnetic design mho relay, use is made of a tuned circuit having time delay to overcome these difficulties. This is referred to as "memory action." Is this memory action feature provided in the electronic relay and if so, how is it accomplished?

The authors explain in the paper that the accuracy of the electronic relay will be better than that of the magnetic relay. The present recommended practice for setting zone 1 of the magnetic relay is to cover 90 per cent of the line section. With the new electronic relay will the accuracy and consistency be sufficient to increase the reach of zone 1 to cover more than 90 per cent of the line section?

Will it be possible to use the new electronic mho relay to control carrier for carrier relay applications? It would be well if the authors would point out how such control is effected; whether it is accomplished by contacts in the carrier control circuit or if it has been possible to effect control by means of biasing control tube circuits in the carrier transmitter by the electronic relay.

R. H. Macpherson: Asbury has pointed out that, since the components of electronic relays have already been developed, their manufacture has been reduced to an assembly process with resultant reduction in cost. On the other hand, since new components are continually being developed which would affect the cost and size of electronic relays, the present preliminary state of the development makes it impossible to predict with any certainty either the cost or the space requirements of the electronic relays.

For nearby faults, where the line voltage may drop to a very low value, memory action is provided in the pulsing circuit. The input of a pulse producing transformer is tuned so that the pulse will continue to occur several cycles after the inception of the fault, thus allowing adequate time for the relay to operate.

The accuracy of the electronic mho relay is not necessarily better than that of the electromagnetic mho relay. This is due to the yet undetermined effect of system transients which may cause false operation unless they can be removed from the measuring circuit. This will be studied in field tests.

No attempt has yet been made to apply the electronic mho relay with carrier-current relaying. It is hoped that, when the application can be made, control will be effected without relay contacts since this would eliminate relay operating time.

Adams called attention to the advantages of consistently fast tripping in connection with high-speed reclosing. This will undoubtedly be realized if the results of the field tests do not dictate the necessity for time delay to obviate errors that might be caused by the system transients referred to previously.

DUE to ever higher standards of service reliability and decreased margin of spare generating capacity, the problem of differential protection for station busses has received considerable attention[1] in the last decade. Installations have been made with simple low-impedance unrestrained instantaneous overcurrent relays fed from conventional current transformers and set for a small fraction of the maximum fault current. The test data included here show that such installations are not safe for a high standard of service reliability because they will trip if residual magnetism and the d-c component of offset current cooperate sufficiently to approach the maximum error current. This problem of d-c saturation of the current transformer cores has led to various unsatisfactory expedients such as 600-pound current transformers[2] or the compromise of making careful calculations[3] of the settings of induction relays for the sake of using standard current transformers even where instantaneous relays would be preferred. This problem has already been solved by direct attack, eliminating part[4] or all[5] of the iron in the magnetic circuit, but each of these systems involves an increase in cost for the mutual reactor that replaces the conventional current transformer, and neither one is readily applicable to existing installations.

A simple differentially-connected relay with a series stabilizing resistor has been used with some success[6,7,8] and has been mentioned in the literature. The scheme as previously applied has been limited in sensitivity by the secondary voltage that can build up across such a stabilizing resistor in the differential circuit on internal faults. The scheme has been investigated analytically,[9] but the results covered too few cases to serve as a general basis for choosing the relay settings and resistance values. Furthermore, no general calculation method has been published to establish the range of usefulness of the scheme. This paper presents a protection system that is an extension of the stabilizing-resistor idea, including the development of a relay that circumvents the limitation of high voltages on internal faults and fully discussing the manner of application for a wide range of current transformers.

Operating Principle

The high impedance of the relay in comparison to the resistance of the current transformer secondaries accounts for the successful operation of this system. To understand how this system provides tripping on internal faults and freedom from false tripping on external faults when one or more of the current transformers is saturated, it is necessary to consider the voltage that appears under extreme conditions at the junction points where the current transformers are connected in parallel and where the high-impedance-relay leads are also connected. See Figure 1.

External Faults

Under external-fault conditions if the current transformers perform ideally, the current in the secondary of the current transformer on the faulted line ("fault CT") is equal and opposite to the vectorial sum of the currents in the secondaries of the remaining current transformers. The voltage at the junction points is zero, and no current flows in the relay, whether it is of high or low impedance. If the "fault CT" saturates, and none of the other current transformers suffer a reduction in ratio, the same secondary current must flow in the secondary of the "fault CT" if the relay impedance is infinite. This secondary current, equal to the sum of the secondary currents in the other current transformers is, however, forced through the "fault-CT" branch impedance by the development of a voltage across the junction points (error voltage) equal to the product of the current and the impedance encountered. This impedance may have three components as follows:

1. Magnetizing impedance of the "fault CT." This is cancelled out by that portion of total primary ampere-turns which balances the secondary ampere-turns. Any excess of primary ampere-turns generates a voltage in the opposite direction to the

** Calculated from average value of highest cycle of relay current.

† This "Equivalent Voltage" value is not significant because the test was made with a series capacitor instead of a resonant impedance.

impedance drop, thereby reducing the error voltage.

2. Secondary leakage reactance. This is quite negligible[10] on the full winding and some taps of bushing-type current transformers; this system should not be used on partial windings without special consideration. Reactance of secondary leads is likewise negligible.

3. Secondary branch resistance equal to the sum of the current transformer secondary winding resistance and resistance of the leads to the junction points. This total resistance is encountered by the secondary current.

Therefore, as shown in the Appendix, the maximum crest voltage that may appear across the junction point is

$$\frac{2\sqrt{2}RI_f'}{N}$$

where

I_f' = maximum external fault current, rms symmetrical

N = number of secondary turns in each bushing current transformer

R = branch resistance for the current transformer having the longest leads to the junction point, winding plus leads

To avoid false tripping on external faults, the relay would be set above this maximum voltage; a safety factor of 2 has been chosen. The rms voltage RI_f'/N based on the symmetrical value of fault current is used, because the relay is insensitive to the d-c component as discussed under Relay Design.

Internal Faults

Under internal fault conditions, the voltage across the high-impedance relay at the junction points approaches the open-secondary voltage that the current transformers will produce. Since the peaks of this voltage wave are quite high, they are in practice limited to a safe value by a Thyrite resistor across the relay, that establishes a voltage ceiling. For successful application, the pick-up setting of the relay must necessarily be below the junction-point voltage produced by minimum internal-fault current. This in general is in excess of the value RI_f'/N, and therefore, the relay, which is set to respond to voltage at its terminals, can distinguish readily between internal and external faults.

Low-Impedance Relay

An analysis[11] has been made of a protective system operating under the same conditions except for the use of a conventional low-impedance relay, and this shows that on external fault where the "fault CT" saturates completely, the relay current can reach 94 per cent of the sum of the secondary currents in the remaining current transformers, since the relay impedance is low in comparison to the secondary resistance of the saturated "fault CT." Thus the low-impedance-relay current is of the same order of magnitude whether the fault is internal or external when saturation occurs, and discrimination between these two types of fault is not readily possible.

One might easily, but incorrectly, assume that for the same external fault the maximum value of error voltage across a high-impedance relay would be that read from the excitation curve, corresponding to this same high value of error current. Fortunately the "fault-CT" circuit acts as a shunt and limits the error voltage to the value RI_f'/N given before.

Additional Margin

The foregoing analysis is based on assumptions that give the limiting condition —that is, the voltage RI_f'/N is the maximum that can be effective on the relay for external faults. However, saturation in general does not exist throughout the entire current cycle, but only on approximately every alternate half cycle. Secondary voltage is thus generated, during the nonsaturated half cycles, that reduces the effective voltage to which the relay responds.

If, as is the case practically, current can flow in the relay, or if any of the current transformers on source connections to the bus ("source CTs") suffer a reduction in effective ratio, the amount of secondary current forced through the saturated current transformer is reduced, and the voltage at the junction points will be less than RI_f'/N, as shown in the Appendix.

With this system, the "source-CT" cores saturate quickly and this greatly reduces the time that the relay must withstand the high error voltage that results from "fault-CT" core saturation in the absence of "source-CT" core saturation. The reason for this quick satura-

Figure 2. Volt-ampere characteristic of Thyrite resistor of bus-differential relay with taps set for four disks. Highest refers to manufacturing variations

tion of the "source-CT" cores, in contrast to their relatively slow saturation with a low-impedance relay, is that with the high-impedance relay the "source CTs" must force nearly all their output current through the "fault-CT" branch, and with offset currents this causes a d-c component, $(\sqrt{2}\ RI_f'/N)\epsilon^{-(t/T)}$ of voltage to appear across the junction points as soon as the "fault-CT" core reaches saturation. This direct voltage required from the "source CTs" saturates all their cores in a subsequent time interval of the same order as the one required for saturating the "fault-CT" core.

These phenomena all produce a margin of safe operation beyond that determined by the value RI_f'/N. Since it is not practical to calculate these phenomena, their over-all effect has been determined by extensive tests made on bushing current transformers under a sufficiently wide variety of conditions to permit interpolation for all the bushing current transformers used in the manufacturer's line of switchgear. The factors thus determined, together with the safety factor of 2, were used in establishing the values of pick-up setting given in Table V.

It is evident from the foregoing that the branch resistance R of the current transformer secondary circuits must be kept to minimum values if the greatest sensitivity of the system is to be attained. In many cases, however, no special precautions will be found necessary in this respect, and in some cases it may be found possible to include additional devices such as ammeters or partial-differential back-up relays. The outstanding advantage of this differential system is that these possibilities are all readily predictable, and the operation of the differential relay is subject to straightforward calculation.

Sensitivity

The safe pick-up setting for the relay having been established in terms of the maximum external fault current, the sensitivity of the protection afforded for low internal fault currents is determined readily by considering the excitation requirements of the current transformers. The primary current must supply the following:

$$\text{Relay pick-up current} = \frac{\text{pick-up voltage}}{\text{relay resistance}} N = I_{rp}N$$

$$\text{Thyrite current} = I_{cp}N$$

$$\text{Excitation current for each current transformer at pick-up voltage} = I_{ep}N$$

The relay resistance is 3,200 ohms. The Thyrite current can be calculated from Figure 2, on the basis of four disks for preliminary purposes. The excitation curves[13] are available from the manufacturer, in accordance with the ASA Standard C57.1 adopted in 1942.[13]

Total primary current required for pickup with n current transformers per phase in the differential circuit is

$$I_p'_{\min} = (I_{rp}+I_{cp}+nI_{ep})N$$

where, for the sake of simplicity the pessimistic assumption is made that the currents can be added as scalar quantities. This is the minimum internal fault current that will be detected by the relay.

* Calculated as for Table I.

** These are $\frac{\sqrt{3}\ (\text{measured crest of relay current})}{2\sqrt{2}}$ which is the rms value of a fully-offset sine wave with infinite time constant.

*** The maximum available setting on the relay was 96 amperes; the relay tripped at this setting.

† This setting barely tripped on one test and almost tripped on another.

‡ This crest differential current occurs 1/4 cycle after the crest of the "fault-CT" secondary current.

§ This crest differential current occurs 7/8 cycle after the crest of the "fault-CT" secondary current.

Initial Installation

The first installation of this bus differential scheme is at the Ripley Steam Electric Station near Wichita, of the Kansas Gas and Electric Company. Requirements for protection of the 60-kv bus at this plant are fairly typical of many applications, although they are by no means so severe in terms of number of connections per bus section or range of fault currents as the capabilities of the new relay system encompass.

Data on Installation

A diagram of the bus is shown in Figure 3, together with approximated resistances of the leads to the various current transformers in the circuit breakers from the junction points.

All circuit breakers on the bus have General Electric 600/5 ampere type *BR* bushing current transformers (BCT) available for use solely in the bus differential circuit, as shown in Figure 3.

Minimum anticipated fault on bus	700 amperes
Maximum external fault current (symmetrical value)	13,400 amperes
Resistance of leads from junction points (circuit breaker 620) to most remote bushing current transformer (circuit breaker 624)	0.43 ohm, 25 degree centigrade 0.49 ohm, 60 degree centigrade
Resistance of bushing current transformer secondary including leads to terminal block in circuit breaker	0.53 ohm, 25 degree centigrade 0.69 ohm, 95 degree centigrade
Excitation characteristic of bushing current transformer	Figure 4

Pick-Up Setting

The pick-up setting of the relay is based on extreme external fault conditions as outlined in the preceding section. The maximum symmetrical voltage across the junction points is thus:

$$R\frac{I_f'}{N}=\frac{13{,}400}{120}(0.49+0.69)=132 \text{ volts}$$

With the safety factor of 2, the relay pickup is set at 265 volts to assure freedom from false operation under extreme external fault conditions.

Sensitivity

The sensitivity of protection afforded for internal faults is determined as described in the previous section. The middle bus section is considered, since, having five connections, it will give the lowest sensitivity

$$\begin{aligned} I_{rp} &= 265/3{,}200 = 0.083 \\ I_{cp} &= 0.367 \\ nI_{ep} &= 5\times 0.33 = 1.65 \\ \hline \text{Total secondary current} &= 2.10 \end{aligned}$$

The total primary current required is therefore $120 \times 2.10 = 252$. This value is sufficiently below the anticipated minimum fault of 700 amperes to assure ample protection.

The maximum number of connections on the bus section that could be accommodated within the desired limits of sensitivity is

$$n_{max}=\frac{I_{pmin}-(I_{rp}+I_{cp})}{I_{ep}}=\frac{(700/120)-(0.083+0.367)}{0.33}=16$$

Thus the possibility of providing protection for any of these bus sections is quite adequate.

The foregoing calculations for this application are based on the theoretical limiting conditions. Tests indicate that for these conditions the additional margins discussed under Operating Principles provide a factor of 2 for these current transformers—that is, the ratio $(RI_f'/N)/(\text{equivalent relay voltage})=2$. This and corresponding factors for other conditions are used in Table V. To take advantage of this margin and obtain increased sensitivity, the pick-up setting could be made $265/2 = 130$ volts and still retain the original safety factor of 2 between pickup and anticipated maximum relay voltage on external fault.

Relay Design

The design of a relay to operate properly in the differential scheme involves certain requirements in addition to high impedance. When offset fault currents occur, or residual magnetism exists in the current transformer core, or both, an appreciable d-c component in the secondary current is present, causing direct voltage to appear across the relay in addition to the alternating component calculated from the maximum external fault current and current transformer secondary and lead resistance. It is desirable to prevent this d-c component from causing the relay to pick up, without reducing the sensitivity of the system to the a-c component of minimum internal fault current. This is accomplished by connecting the relay element in series with a capacitor and suitable reactor such that the entire combination is resonant at the fundamental power frequency; the d-c component of secondary current is blocked from passing through this relay circuit by the series capacitor. Thus the impedance of this circuit is made high, and essentially resistive.

The resonant circuit was not adopted for the purpose of riding over the transient error voltage produced by the saturated current transformers, but solely to block the d-c component of voltage, and may thus be likened to the circuits used in connection with distance relays to avoid over-reach on offset fault currents.

In order to provide resistance to closure on shock, and to take advantage of the reasonably high power levels available to the sensitive unit, it was decided to employ a robust plunger-type device. Since the inductance of such a relay varies with the plunger position which determines the pick-up setting, the coil is energized through a rectifier to prevent upsetting the resonance of the entire relay circuit when the plunger is moved.

The Thyrite resistor connected in parallel with the circuit of the sensitive unit consists of a tapped stack of disks. The tap setting is chosen so that the resistor draws only a small current at the pick-up setting of the sensitive unit. For high internal faults that tend to produce high voltages in the secondary circuit, the Thyrite draws high current, thereby establishing an effective ceiling on the voltage that can be attained across the junction points. This ceiling is in general set at or below a peak voltage corresponding to 1,500 volts rms, which is considered allowable momentarily in switchgear secondary wiring. It should be noted that this ceiling voltage lasts only for the short interval required to pick up the relay on an internal fault and operate the auxiliary tripping relay that short circuits the secondaries of the current transformers as shown in Figure 5.

The presence of the Thyrite resistor together with the resonant characteristic of the sensitive-unit circuit has a tendency to slow the operation of this element to as much as 3 to 6 cycles by retarding the current build-up in it. In order to improve the tripping speeds of the entire system on high internal faults, an additional relay unit is connected in series with the Thyrite, operating on the current shunted through this circuit. Thus shorter tripping times for such faults are obtained, in the range of 1 to 3 cycles. Tests have been made to permit a choice of setting for this Thyrite relay unit that is safe against false tripping on the most adverse conditions of offset current and residual magnetism combined.

Figure 6 shows the complete relay assembly.

Test Procedure

Since the tests were made for determining the maximum value of error voltage, it was necessary to set up the most unfavorable conditions.

Offset currents are commonly recognized as the cause of current transformer errors, so these were provided by using: a synchronous switch to control the starting phase angle to give full offset; a 5-ton iron-core reactor with air gap to give a long time constant; and a stacked multiturn primary of copper bars to keep the current requirements below 10 per cent of station rating thus minimizing the effect of the resistance of the supply circuit and the station transformers on the time constant. Figure 7 shows the general arrangement of apparatus for testing one "fault CT" with four other current transformers.

It has already been shown[14] that residual flux from a previous fault can remain at a high value, and the wide use of instantaneous reclosing necessitates provision for the full value, which may be as high as 80 kilolines per square inch. Therefore the test circuit, Figure 8, was adapted to saturate all the cores in the same direction with direct current before each test. Since nearly two-thirds of the flux capacity of the "fault-CT" core was used by this residual flux following full direct current saturation, primary waves having only one-third the time constant that would otherwise be necessary were adequate to complete the saturation of the core.

Figure 6. Type PVD differential voltage relay

87L—Sensitive unit
87H—Thyrite unit

During external faults, the current in the "fault CT" is in the opposite direction from that in the remaining "CTs," so the residual can be additive in the "fault CT" and subtractive in the others. This is the worst condition, and the use of the synchronous switch made it possible to insure this relation.

In the application of multirestraint relays the current distribution has been an important consideration. With the simple high-impedance differential relay, a uniform current distribution among all the "source CTs" gives the highest error voltage and therefore the most unfavorable condition, because it minimizes the voltage drop (RI_f'/Nm) in each one of these m "source CTs" and thus causes it to maintain its normal output current at more nearly full value and for a slightly longer time. Saturation of the "source CTs" in any form of differential relaying is a help rather than a hindrance because it is always less severe (except for a possible half-cycle effect of additive residual flux) than that of the "fault CT" and therefore it can only reduce the false differential current or voltage, but never increase it. The largest number of sources is therefore the most unfavorable condition; tests were carried up to eight "source CTs" with primary-current distribution 2, 2, 2, 2, 1, 1, 1, 1 to approximate the most unfavorable current distribution expected in service.

Each sample current transformer of a given size was tested for exciting current, and the one with the highest value was used as a "fault CT" in setting up that size, to give the most unfavorable condition.

External-fault tests to determine the setting necessary for avoidance of false tripping, and internal-fault tests to check the crest voltage on the insulation, were carried to 160 amperes secondary as compared with the limit of 100 amperes often taken as the basis for choosing current-transformer ratios for differential protection. Various measured values of lead resistance were tested to provide data for the expected range of application conditions.

Test Results

Table I and oscillograms 76, 103, and 131 of Figure 9 give typical data from the tests that were made for the purpose of checking the theory and determining the safe settings of the relay. Lines 1 and 2 cover the 69-kv 600/5 ampere current transformers with preliminary values of lead resistances, to be used at the Ripley Station mentioned before. Although for the current level and lead resistance expected in service, the crest value of error voltage is 76 per cent of the predicted maximum, the effect on the resonant circuit is only about 10 per cent of the predicted crest value $2\sqrt{2}\ RI_f'/N$ on the basis of a fully-offset wave with infinite time constant. This extra margin as compared with the predicted poorest performance of these current transformers with, for example, an electronic relay responding to instantaneous values, has already been explained under the sections on Operating Principles and Relay Design.

The high-current tests were made with a time constant of about 0.05 second, and the medium- and low-current tests at 0.11 to 0.15 second. As will be seen from the oscillograms, either of these time constants gives quick saturation of the "source-CT" cores as shown by the fact that the half cycles of secondary current in the offset direction are greatly diminished; so a change in time constant would only change the time required for recovery but would not change either the crest or equivalent value of error voltage to any great extent. The reason for this is that the use of opposite premagnetiza-

† Not measured.

tion of the "fault CT" and "source CTs" in the test insures that for most conditions the "fault CT" will saturate completely during the first cycle of offset external-fault current, and that the "source CTs" will remain unsaturated as long as possible, thus giving both a crest value and an equivalent value which a longer time constant would not increase. A time constant even considerably shorter would not affect the crest value with residual flux appreciably, but it would tend to reduce the equivalent value by permitting more rapid recovery from the saturated condition.

Lines 4 and 5 of Table I are included to show the effect of the relative polarity of residual flux and offset external-fault current on the crest value of error voltage. These show about 60 per cent reduction in crest value, although the reduction in equivalent voltage on the resonant-circuit unit would be much less. All of the tests used as a basis for calculation of proper relay settings were made with the residual and offset additive in the fault-current transformer and subtractive in the source-current transformers.

High-Impedance versus Low-Impedance Relay

Lines 3 and 4 of Table I are included for comparison with Table II which shows the performance of the same typical bushing current transformer from the standpoint of application of a low-impedance instantaneous differential-overcurrent relay. These lines show that the effect of the error voltage on the resonant-circuit unit is only about 11 per cent of the measured crest voltage, so that the relay can safely be given a setting that is very low in comparison with the voltages shown in Table IV which covers internal faults. This large margin between external-fault voltage and internal-fault voltage is in contrast to the situation with a low-impedance relay as discussed under Operating Principles and shown in Table II.

Lines 2 and 3 of Table II in comparison with line 4 show that the relative polarity of residual and offset makes more difference in error current than does a reasonable value of lead resistance. The apparent reversal of "source-CT" secondary current between oscillograms 137 and 144 of Figure 9 is due to an intentional reversal of oscillograph leads.

Thyrite Circuit

Table III shows typical test data for calculating the proper setting of the Thyrite tap and of the Thyrite relay unit. This unit is used only to increase the speed of operation for severe faults where that is desirable; the sensitive unit will always operate, but a-c core saturation and the necessary presence of the Thyrite limiter prevent the equivalent applied voltage from reaching the high multiple of pickup that would be necessary for 1-cycle operation with the resonant circuit. The number of Thyrite disks recommended for use in service is twice the number used in test to determine the threshold of relay pick-up, so that a 2/1 margin is obtained; the tests for this purpose were made with the residual and offset additive in the "fault CT" and subtractive in the "source CTs."

Internal Faults

Figure 10 and Table IV show the wave forms and measured values of voltage and current, and the operating times, from typical internal-fault tests. Comparison with the corresponding equivalent relay voltage or the number of Thyrite disks in Tables I and III shows the margin available against false tripping on external faults or failure to trip on internal faults. Core saturation introduces a variation of nearly one cycle in the tripping time, because it may happen to prevent any appreciable output voltage on the first cycle of a fully-offset internal-fault current. However, even a relatively small negative loop of current at the end of the first cycle will saturate the core in the opposite direction because of the high impedance of the relay circuit, thus giving a half-cycle output limited mainly by the Thyrite; subsequent cycles will have substantially full output voltage on each half cycle because the core is saturated in opposite directions during alternate half cycles in spite of the presence of the d-c component. Oscillograms 79, 80, and 81 were taken with offset current and without any attempt to reduce its effect, so they show normal performance as regards the voltage obtained; the operating times are longer than normal because the Thyrite relay unit had not yet been connected when they were taken, and also because the voltage settings used for oscillograms 80 and 81 are higher than would normally be used.

Application Data

Many applications in the transmission-voltage class will be found to have adequate sensitivity on the basis of the simple RI_f'/N calculation; the only information necessary is the excitation curve corresponding to Figure 4, the secondary resistance, the resonant-circuit impedance, and the 4-disk Thyrite impedance, Figure 2. All effects of offset should be neglected in this calculation. This procedure will show successful application on some existing busses, regardless of the age or type of circuit breakers.

For more difficult applications such as the lower-voltage classes, advantage may

be taken of the additional margins discussed under Operating Principles. This is done by calculation based on the results of factory tests on transformers having an excitation curve similar to the ones in question. These calculations, based on assumed values of lead resistance, have been made for all bushing current transformers used with the listed circuit breakers of one manufacturer. The resulting data are available in the form of Table V. Similar data for bushing current transformers having excitation curves of different shapes must be based on similar tests with those transformers.

The ratio

$$\frac{\text{maximum external-fault current}}{\text{relay pick-up current}}$$

for the five examples in the table varies from 75 to 130; the lowest ratio among the remaining 55 ratings now in production is 14.

Conclusions

In conclusion it is pertinent to summarize certain outstanding advantages of the bus differential system described in this paper.

1. Standard relaying type bushing current transformers are used, for which only the open circuit excitation data and secondary winding resistance need be known.

2. The system gives high-speed protection for moderate and severe faults.

3. Performance for specific applications is subject to simple calculation, which will show a large margin in many cases.

4. The operating conditions imposed on the current transformers by the high-impedance relay give rise to margins not available with a low-impedance relay

and these margins have been determined by test.

5. Many applications with new or old current transformers may be made successfully with careful planning, even though preliminary examination based on the RI_f'/N voltage drop may indicate that the system will not apply.

6. In limiting cases, it may be necessary to reduce the maximum secondary resistance by making the leads short and large. This can usually be done easily in the planning stage.

7. Paralleling of the current transformers should be done as near the circuit breakers as possible. Only four conductors need be brought to the relays from the junction point to provide 3-phase protection of a bus section. The leads may be paralleled in the switchyard or even at the circuit breaker terminals, with consequent saving in cost.

8. Designers may wish to use the same standard current transformers jointly for other functions; the performance of the system under these conditions can be calculated, but consideration must also be given to the hazards of false operation due to extra connections and errors in testing the added devices.

9. Protection is extended easily if the number of connections to the bus is increased.

Definitions

e_d = voltage between junction points for external fault, instantaneous value.

i_d = differential current in whole relay, instantaneous value.

i_f = "fault-CT" secondary current, instantaneous value.

i_f' = "fault-CT" primary current, instantaneous value.

$i_{(n-1)}$ = secondary current in each "source CT," instantaneous value.

$i'_{(n-1)}$ = primary current in each "source CT," instantaneous value.

I_{cp} = current in current relay and Thyrite resistor at pick-up of sensitive relay, rms value.

I_{sp} = exciting current of each "CT" core at pick-up of sensitive relay, rms value.

I_f = "fault-CT" primary current, rms symmetrical value.

$I_{sp'm/n}$ = primary current at pick-up of sensitive relay, rms value.

I_{rp} = current in resonant circuit at pick-up of sensitive relay, rms value.

H_f = magnetomotive force in "fault-CT" core.

$H_{(n-1)}$ = magnetomotive force in each "source-CT" core.

m = total number of source current transformers per phase.

n = total number of current transformers per phase.

N = secondary turns of each transformer (primary = 1).

R = resistance of longest "CT" branch between junction points, secondary winding plus leads.

R_d = resistance of differential relay.

ϕ_f = flux in "fault-CT" core.

$\phi_{(n-1)}$ = flux in each "source-CT" core.

T = time constant L/R of primary circuit.

Appendix

Open-Circuit Voltage Across Junctions with External Fault

It is assumed that all "CT" branch resistances are alike, and that all the "source-CT" currents are equal; these assumptions permit conversion from the actual circuit of Figure 11(a) to the equivalent circuit of Figure 11(b).

Noting that the induced voltage in the "source-CT" branch of Figure 11(b) is the same as that in each of the $(n-1)$ "source-CT" branches of Figure 11(a), the current-transformer loop of Figure 11(b) gives

$$10^{-8}N\frac{\phi_f}{dt}-Ri_f+10^{-8}N\frac{d\phi_{(n-1)}}{dt}-\frac{R}{n-1}i_{(n-1)}=0 \qquad (1)$$

For this condition the driving voltage in this loop is divided between the "fault CT" and the $(n-1)$ "source CTs," and

$$e_d=10^{-8}N\frac{d\phi_{(n-1)}}{dt}-Ri_{(n-1)}$$
$$=-10^{-8}N\frac{d\phi_f}{dt}+Ri_f \qquad (2)$$

If it be assumed that core saturation reduces $d\phi_f/dt$ toward zero regardless of H_f, the term $-10^{-8}N\frac{d\phi_f}{dt}$ decreases, and e_d approaches the limit

Figure 11. Circuit for analysis of external-fault conditions

a—actual
b—converted

$$e_d=10^{-8}N\frac{d\phi_{(n-1)}}{dt}-Ri_{(n-1)}=Ri_f \qquad (3)$$

If it be assumed further that the "source CTs" perform ideally and are not subject to core saturation

$$H_{(n-1)}=0=i'_{(n-1)}-Ni_{(n-1)} \qquad (4)$$

and

$$i_{(n-1)}=i'_{(n-1)}/N$$

Now $i_f'=(n-1)\,i'_{(n-1)}$, and for open-circuit conditions $i_d=0$, so

$$i_f=(n-1)i_{(n-1)}=(n-1)i'_{(n-1)}/N=i_f'/N \qquad (5)$$

Substituting in equation 3

$$e_d=Ri_f'/N \qquad (6)$$

If $i_f'=I_m[\cos\ \alpha E^{-\theta/T}-\cos\ (\theta-\alpha)]$ and $\alpha=0$ (fully offset wave) the maximum value of i_f' is $2\ I_m$. Since for a sine wave $I_{mf}'=\sqrt{2}I_f'$, the maximum value of i_f' is $2\sqrt{2}I_f'$

Then

$$e_{d\max}=2\sqrt{2}RI_f'/N$$

Change in Voltage Across Junctions, Due to Presence of Relay

If $R_d<\infty$ and the same assumptions are made,

$$i_f+i_d=(n-1)i_{(n-1)}$$
$$=(n-1)i'_{(n-1)}/N$$
$$=i_f'/N$$

$$i_f=(i_f'/N)-i_d$$

$$e_d=Ri_f'/N-Ri_d$$

which is smaller than before.

Discussion

L. F. Kennedy (General Electric Company, Schenectady, N. Y.): The authors of this paper are entitled to a great deal of commendation because they have approached the problem of high-speed bus differential protection from a new viewpoint and have found a solution which avoids the disadvantages encountered with special types of current transforming devices or the hazards of complex determination of saturation effects. The difficulties encountered in the past with high-speed bus differential relaying have been recognized for a long time and the generally accepted theory is well paraphrased by the remark, "Bus-differential relaying is limited by the current transformer performance." Many attempts have been made to provide a simple method of evaluating the current transformer performance. Other attempts have been made to overcome known or suspected saturation effects. Still other solutions were offered using special designs of transformers to obtain nonsaturating performance.

The authors now show that the previously accepted opinion that conventional designs of current transformers were totally inadequate for the bus protection was in error. By simply changing the relay sensitivity from amperes to milliamperes, that is, replacing a current coil by a voltage coil, it is shown that good sensitivity can be obtained for internal faults with adequate safety against incorrect operation on external faults.

The arrangement used has an apparent paradox in that operation for internal faults means essentially open circuit operation of the current transformers and hence requires the voltage controlling action provided by the Thyrite resistors. On the other hand, normal operation and operation during external faults will be the usual, closed-circuit, circulating-secondary, operation with which we are all familiar.

Unquestionably, there have been cases where the application of bus differential protection has been postponed because none of the previous solutions seemed attractive. Now, with a bus differential relay system available for operation from standard bushing-type current transformers, there is no reason why bus sections should not be provided with high-speed protection comparable to that provided for line sections.

W. A. Lewis (Illinois Institute of Technology, Chicago, Ill.): The essential feature of the bus-differential protection method described by the authors of this paper is the use of a nonlinear relay characteristic which is sensitive under minimum fault conditions but is insensitive for external faults. This basic concept is not new, and has been used in one form or another in various types of relays in the past. The novel features of this paper are the means which have been used to accomplish this result. The features are illustrated in Figure 5 of this paper. The essential elements are as follows:

1. The use of a resonant circuit.
2. The use of capacitors to obtain desired circuit characteristics.
3. The use of dry-type rectifiers.
4. The use of a Thyrite resistor element.

The changes which have taken place in the relaying art in the last 15 years may be summarized by stating that probably no relay engineer of 15 years ago would have considered the use of any one of these four elements in a current protective circuit. Capacitors were considered unreliable, and resonant circuits as dangerous in a current or protective circuit. The use of dry-type rectifiers and Thyrite in such circuits would have been rejected as dangerous. The possibility of failure and the uncertainty of the characteristics would have been the principal reasons for rejection. Yet the authors of this paper have presented a method of protection which is essentially dependent upon the use of these devices for its operation, and they have felt it unnecessary to offer any apology for the use of these devices or to justify them individually. The general acceptance of devices of this kind has gradually come about during the past 15 years without any specific recognition of that fact.

In the appendix, equations are given for the open-circuit voltage across the relay junctions with an external fault present. In these equations, voltage and current are given in meter-kilogram-second units, but magnetic flux is given in centimeter-gram-second units. This results in the presence in the equations of the factor 10^{-8}. Such factors are a nuisance, and can be avoided by the complete use of the meter-kilogram-second system. As official sanction has now been given to the use of this system, I would like to urge the authors of this paper and other relay engineers to simplify their analyses by the universal use of this system. Only very little study is required to become familiar with the meter-kilogram-second units of flux and other quantities which are different from those in common use in equations in practical units.

A casual review of Figure 2 of the paper does not show clearly the very large change in resistance of the Thyrite resistor which occurs as the impressed voltage changes. The curve looks nearly like a straight line, which would correspond to a resistor which did not change in value. The very large range of resistance utilized in this case can be visualized if the resistance is computed. From the figure, the resistance is found to be about 6,000 ohms at 120 volts, but less than 300 ohms at 400 volts. This is a resistance change of approximately 20-to-1, as the voltage changes less than 4-to-1.

A qualitative basis for determining the margin between trip and nontrip conditions may be obtained by referring to Figure 1 of the paper. In that figure, an external fault is shown at E. For such a condition, current is fed into the bus from the generator and from circuits L and S, but all current must be fed out to the fault at E. If the current transformer at F saturates completely, so that there is no voltage output or current output from the secondary of this transformer, the apparent exciting impedance, as viewed from the secondary terminals, is zero, and the only impedance is the secondary winding resistance and leakage reactance, if any. For bushing current transformers, the authors have assumed that the leakage reactance is zero, and so have taken the impedance as the secondary resistance. If the fault is moved from E to the bus side of the circuit breaker on the same feeder, but with no other system changes, and the circuit breaker on this feeder is opened, the primary currents in all the source current transformers will be the same as for the fault at E. In this second case, however, the

fault is an internal one for which the relay should trip. Now the apparent impedance of the current transformer F is that measured from the secondary terminals with the primary circuit opened, as determined for a typical case from Figure 4, by dividing the voltage by the current. This impedance includes the secondary resistance and leakage reactance, if any, and, in addition, the true exciting impedance. The difference in impedance as seen from the secondary terminals of the current transformer F for these two conditions must be sufficient to provide selectivity for the relay.

C. E. Asbury (The Commonwealth and Southern Corporation, Jackson, Mich.): It is encouraging to see further development work being done on bus protection. There is a definite need in the industry for a reliable bus protective arrangement to provide phase and ground protection having reasonably good sensitivity. Such a bus protective scheme should make use of standard bushing current transformers available on existing circuit breakers as the one outlined in this paper. It is hoped that such a protective arrangement can be kept simple.

It appears that rather high voltages will be encountered on the current transformer secondaries where this bus protective scheme is used perhaps as high as 1,000 to 1,500 volts may not be uncommon for heavy short circuits. This high voltage will appear across the secondary of the "CTs" as well as across the relay at the switchboard, stressing the insulation and may produce breakdown in existing current transformer insulation where the "CTs" are quite old. It would be well if the authors would state whether any special insulation is required on an installation of this scheme. The relay committee is considering a test voltage of 1,500 volts for new relays, and a voltage test less than this for older installations in the field. It appears questionable whether other relays in this circuit could withstand these high voltages without causing difficulty.

The statement is made in the paper that this system should not be used on partial windings of current transformers without special consideration. Apparently this would mean using the full winding up 120/1 ratio on 600-ampere bushing current transformers and a 240/1 ratio on 1,200-ampere current transformers. Apparently this is necessary to avoid autotransformer action of the tapped multiratio transformers. It would be helpful if the authors would point out how this affects the relay sensitivity.

It would also be helpful if the authors could elaborate on the following points concerning the application of this new bus protective relay:

1. Do these relays provide for phase and ground fault protection and how many relays are required for a complete phase and ground protection?

2. Have standard adjustable ranges been established or does each application require special design?

3. Can these relays be applied on meagerly grounded systems having impedances in the system neutral? What are the limitations to such applications?

4. In equation

$$\frac{2\sqrt{2}RI_f'}{N}$$

is not the branch "CT" leads having the largest RI_f' product the one to be considered for external faults in setting the relay instead of the maximum I_f' and largest R which might not be associated with each other for any external fault conditions?

5. Since the sensitive tripping relay is a voltage relay and may be connected to two rather long leads between the switchboard and the switchyard it appears that this circuit would be subject to induced voltages due perhaps to the flow of heavy ground fault currents. Would the authors recommend that any precautions be taken against these induced voltages in an installation?

H. T. Seeley and **Frank von Roeschlaub**: Kennedy has aptly characterized the distinctive and fundamental characteristic of the new protective system in terms of changing the relay sensitivity from amperes to milliamperes, and the calibration from current to voltage.

Lewis points out the combination of relatively new elements necessary to the schemes' successful operation. Fortunately for the acceptance of the scheme, the resonant circuit, capacitors, dry-type rectifiers, and Thyrite resistors in current transformer circuits, have each been accepted separately and have accumulated a performance record. It is a tribute to protective engineers who have to operate power systems with these devices, that progress has not been impeded simply because of their newness when first introduced. As authors, we now appreciate the advantages that Lewis points out for the meter-kilogram-second system.

The basis for discrimination has been analyzed concisely by Lewis. The difference in impedance of the current transformer on the feeder in question can be relied upon after the first cycle of internal fault current during which residual core flux may decrease the magnetizing impedance below the values calculated from Figure 4. The effect of this difference in impedance can be seen by comparing the relay equivalent voltages of Table I for severe external faults with the corresponding voltages of Table IV for internal faults of less than current-transformer rating.

The insulation strength of current transformers, which concerns Asbury, is covered by paragraph 4.047 of ASA Standard C57.1, which requires new transformers to be capable of withstanding continuously either 3,500-volts crest or operation at rated current with the secondary open, whichever is lower. It is common practice to test installed apparatus at 75 per cent of the original value, which would be 2,600-volts crest in this case, and this allows about 20 per cent above the crest value that was taken as a basis for application of this scheme. The crest value in most installations would be lower. It is the authors' belief that standard current transformers, control cable, and panel wiring are adequate for this service, subject to an initial test and infrequent periodic tests of this insulation.

While the use of other relays on current transformers used for differential protection is not normal, it is within the capabilities of the scheme on some installations and therefore the question of voltage stress on other relays is proper. Relays for the common functions, adequate for a field test of 2,500 volts, should be specified where needed for use in these circuits. The differential relay is already designed for this test.

The caution against use on partial windings was based on lack of knowledge of the leakage reactance of these partial windings, but the problem of voltage also warrants consideration. Where all current transformers are of the same ratio the use of the full windings instead of taps will allow even lower voltage setting of the relay and usually a better instead of a poorer sensitivity of protection. For the remaining cases such as 1,200/5 current transformers which must be paralleled on 600/5 taps with 600/5 current transformers on the same bus section, the voltage problem can be solved by connecting fewer Thyrite disks, at some slight loss of sensitivity, which can be calculated.

In answer to Asbury's numbered questions.

1. Three relays are required for combined phase and ground protection of a section of 3-phase bus.

2. The standard adjustment range of 100–400 volts for the sensitive unit and 4–100 amperes for the Thyrite unit are calculated to cover 98 per cent of one manufacturer's modern ratings of circuit breakers in typical installations.

3. The calculated sensitivities of typical installations with these circuit breakers range for 8 to 57 per cent of current transformer primary rating, and average 19 per cent, so the sensitivity is believed adequate for the majority of impedance-grounded systems (not including Peterson coils).

4. In the equation for maximum external-fault voltage it is proper, as Asbury suggests, to associate each external-fault current with its own branch resistance and use only the largest product, and this will permit the greatest sensitivity. The expression used in the paper, associating the maximum external-fault current with the maximum branch resistance, was adopted to simplify the calculations and will in some cases indicate a higher setting than necessary, but probably the refinement would be applied only if the simpler method showed inadequate sensitivity.

5. The voltage induced by heavy short circuit currents can be neglected in comparison with the relay setting of 100–400 volts if the precaution is observed of running all four leads from the junction to the three relays through the same conduit, so that the longitudinal voltages in the two leads of any one relay are opposite with respect to the circuit of that relay and approximately equal.

Relay Preference Lockout Circuits in Telephone Switching

AMOS E. JOEL, JR.
MEMBER AIEE

IT IS a well known principle in telephone switching practice that equipment be provided in sufficient quantity to serve the calls offered during a busy hour. Under normal conditions only an occasional call should encounter a lack of facilities to handle the call. Usually during a busy hour an average of from 5 to 15 per cent of the telephone lines are in use. Therefore, switching linkages and equipment are engineered to accommodate approximately the corresponding number of simultaneous calls. It is the object of this paper to describe, with examples, some of the philosophies which are employed in the design of one of the circuit functions which disposes available facilities among telephone users who unknowingly are competing for them.

In general, telephone connections are established over a progression of switching linkages, one or more of which constitutes a switching stage. In common control switching, as calls originate or reach a switching stage, it is convenient to serve them one-at-a-time in order that the quantity of control equipment required will not be excessive. With a small quantity of control equipment greater flexibility of control may be provided at relatively little additional cost. A switching stage may be subdivided in order that several calls may be handled simultaneously within a switching office or unit. It is possible for several calls originated simultaneously to reach the first switching stage at the same time. Thereafter several calls may reach a later switching stage or subgroup simultaneously as a result of having been served by different subgroups in the preceding stage. However, within a subgroup regardless of the stage order or size, calls are handled on a one-at-a-time basis.

There are a number of "distributive" functions in switching which have to do with the serving of calls as they originate or reach various stages at which a number of switching linkages or equipment components are available for use. Electromechanical switches have been employed in performing many of these functions. In common control switching where greater speed is required in performing these functions, relay circuits are used. One of the distributive functions which is encountered in this type of switching is described in this paper. This function is known as the "preference lockout."

Relay Preference Lockout—General

The preference lockout may be defined as the switching function which upon direct request permits service to only one of a plurality of switching linkages. The term "preference" is used in the name of this function to distinguish it from "line or signal" lockout such as used in telephone switching to prevent troubles in outside plant from holding switching equipment out of service. To a preference lockout circuit, switching linkages or equipment components are usually sources of telephone traffic seeking the services of a particular circuit or function available for the common use of the group of sources. There are many types of preference lockout circuits employed in telephone switching.

These circuits contain some or all of the following design characteristics:

1. Respond to a single indication, preferably over a single lead (in a grounded return system), as a request for service from a source.
2. Serve only one request at a time.
3. Serve requests from all sources with as little inequality of delay as possible as a result of preference position.
4. Complete the serving of a source upon the withdrawal of its original request or maintain connection with the common serving circuit independent of the original request from the source.
5. Detect and indicate abandonment of a request while it is being served.
6. Contain no inherent properties which under some conditions prevent serving or being served.

These characteristics of preference lockout circuits may be understood from the following description of typical applications.

End Relay Preference Lockout Circuit

In manual switching using the straightforward method,[1] calls arrive more or less at random at "B" switchboard positions in the call completing office. To provide rapid service, some switchboards are designed to connect automatically the incoming trunks to the operator position and telephone set.

Referring to Figure 1, the incoming trunk circuit detects when the trunk is seized at the originating office and places ground on the *ST* lead to the preference lockout circuit. An operator serves calls on any one of the 48 incoming trunks which appear as single plug-ended cords at her position. Two relays, an *ST* and an *LS* relay, are provided in the lockout circuit for each trunk. The ground on lead *ST* operates a relay *ST* to battery over a chain of break contacts on the *LS* relays associated with the higher numbered trunks. With relay *ST* operated, a series path is closed through the winding of relay *LS* associated with this trunk and the winding of relay *A* to ground on the break contact of relay *B*. Relays *A* and *LS* operate in series. When relay *ST* operated it opened the operate path for

Paper 48-312, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted August 3, 1948; made available for printing September 21, 1948.

AMOS E. JOEL, JR. is with the Bell Telephone Laboratories, Inc., New York, N. Y.

Figure 1. End relay preference lockout

LS relays of any trunks to the left, preventing them from operating. Similarly when relay *LS* operates it opens the battery path which prevents the *ST* relays of any trunks to the right from operating. In this manner, all other trunks are locked out.

Thus one call would be served. The position and operator telephone set is now connected to the trunk through one or more contacts multiplied on the *LS* relays. Relay *B* operates through relay *A* after the latter has supplemented the grounds for holding itself and an *LS* relay operated.

While this call is being served by the operator, others may arrive on any of the other trunks. A most important attribute of a lockout circuit is the order in which calls are served. This order is based on three principal factors:

1. The time when service is requested relative to other requests.

2. The positional order in the lockout preference.

3. The nature of the lockout circuit action.

In the particular circuit under consideration, as calls arrive on trunks to the right of the trunk being served, no action occurs in the lockout circuit since battery for the associated *ST* relays is cut off at the break contact of the operated *LS* relay. However, calls arriving on trunks to the left of the one being served may operate their associated *ST* relays, thereby preparing them to be served.

When service has been completed for a call on a trunk connected with the position and operator, the associated *ST* relay releases. The *LS* relay associated with the next operated *ST* relay to the left will operate in series with the *A* relay. (Continuity contacts on the *ST* relays insure that relay *A* will not release when a new *LS* relay is being inserted in its holding circuit.) The *LS* relay of the trunk just served will release. Thus the chain of contacts on the *ST* relays serves to insure that only one *LS* relay operates at a time.

Since service is permitted only to trunks to the left and these trunks are gradually served, the condition will eventually occur where the release of an *ST* relay will no longer provide a path through an operated *ST* relay to hold relay *A*. Relay *A* will release immediately, opening its holding circuit which is also the operating circuit for *LS* relays. Relay *B* is also permitted to release, but being slow to release it prevents the immediate reoperation of relay *A*. During this interval when all *LS* relays are normal, the *ST* relays of all trunks requesting service are permitted to operate, particularly those to the right which were formerly locked out.

The minimum release time of relay *B* is greater than the maximum operated time of any *ST* relay to insure that any trunk requesting service will have ample time to operate its *ST* relay. When relay *B* finally releases, the process of serving may again begin. End relay *B* of this lockout circuit performs a function essential in all preference lockout circuits, namely, no switching linkage may, as a result of normal circuit operation, be perpetually locked out due to action within the lockout circuit, produced by other linkages being served.

The order in which this type of lockout circuit serves calls should be noted. If the serving of each call is completed before the arrival of the next call, then calls are served in strict time order. However, if calls arrive while a call is being served, all calls waiting on higher numbered trunks are served before any lower numbered trunks, for example, calls arrive in the following order on trunks 5, 4, 2, 6 and 1 while a call is being served on trunk 3. Subsequently, these calls are served under control of the end-relay type of lockout circuit in the order: 4, 5, 6, 1, 2. If the call on trunk 3 is finished being served before the calls arrive on trunks 4, 2, 6, and 1, then the calls are served in the order: 5, 6, 1, 2, 4.

Double Chain Preference Lockout Circuit

Throughout the various crossbar switching systems[3,4] the double chain lockout circuit is used to a considerable extent. In these systems, each of the control devices at a given stage, such as markers, must work with all the switch frames in that stage. Hence, markers compete with one another for access to these frames to obtain exclusive control of the operation of crossbar switches located thereon.

In this circuit, shown in Figure 2, only one relay is associated with each marker served by the frame. When a marker requests access to the frame, the associated lead *ST* is grounded. The associated *MP* (marker preference) relay operates provided there is no other marker being served at this time.

Battery is supplied to the *MP* relay over a chain of break contacts on the higher numbered *MP* relays. An *MP* relay in operating locks independent of this break contact chain. Continuity contacts are used between the lockout and locking paths to insure that the operate path will not open until the lock contact is closed if an *MP* relay operates after a

Figure 2. Double chain preference lockout

Figure 3. Use of connector relays with preference lockout

higher numbered *MP* relay is operated. The order of serving of this type of lockout circuit is the same as that of the end-relay type of lockout circuit.

Chains of transfer preference contacts (only one shown) may connect the switch frame points with the marker being served. Usually a great many leads must be connected through between a marker and a switch frame. Figure 3 shows how a single transfer preference chain on the lockout circuit may be used to control a connector circuit to obtain a larger number of paths between the marker and the switch frame.

Gate Preference Lockout Circuits

Gate lockout circuits are used in crossbar systems where it is desirable to serve equitably calls in the order of arrival. This is particularly true in the controllers reached first by calls entering the switching equipment (lines or incoming trunks). The action of this type of circuit permits all calls waiting at the time the gate closes to be served before any calls which may arrive later.

Figure 4 shows a gate lockout circuit. The preference relays *H* are operated on requests for service when the gate is open (relay *GT* normal). Once an *H* relay operates, it locks independent of the gate relay *GT* and then starts the operation of relay *GT*. Relay *GT* in operating closes one or more preference chains to serve the source operating the lowest numbered *H* relay.

Connector relays may be employed if larger numbers of leads are required for the service. When the gate is opened several sources may be awaiting service. In this case each source operates its associated *H* relay. The *GT* relay is slow enough in operating to cover the difference in operating time between the slowest and fastest *H* relay to insure against perpetual lockout when competition exists. When several *H* relays are operated the gate is held closed as long as any of these *H* relays remain operated. Thus all sources waiting when the gate was momentarily opened must be served before the sources that requested service since the gate closed may be served. Service to those within the gate is in order starting from the lowest numbered operated *H* relay. Again assuming calls requesting service from sources in the order 5, 4, 2, 6 and 1 while 3 is being served, they will be served in the order 1, 2, 4, 5, and 6 since all are permitted into the gate when it opens at the end of the service for source 3. If the service of source 3 is completed before the requests are made by sources 4, 2, 5, and 1 then they are served in the order 5, 1, 2, 4, and 6.

Gate Check Preference Lockout Circuits

The gate type lockout circuit introduces a new element in lockout circuits, namely the gate relay. An individual gate contact is used by a source on each request for service. Should this contact become open due to a trouble condition (dirt or maladjustment) the associated source will be perpetually locked out. Where checks may not be made in another manner to insure against this condition, a gate-check type of lockout circuit, described in the following may be used. A check of the type to be described is secured at the cost of a relatively small increase in time required to give service and the addition of relays.

The splitting relay *SP* is added to the gate lockout circuit (See Figure 5) to enable a request for service from any source to operate all the individual lockout relays, here designated *V*. This is accomplished through its splitting relay contact and the *SP* relay contacts associated with all other sources. When all *V* relays operate, end relay *VT* operates. This indicates that a check of all gate and splitting relay contacts as well as the windings of all *V* relays has been successful. Circuit means, not shown, are provided to indicate a failure to check when at least one but not all *V* relays operate. Relay *VT* in operating, operates relay *SP*. Relay *SP* in operating opens the paths which operated *V* relays associated with sources not requesting service. With some of the *V* relays now releasing the original operate path for relay *VT* is opened. However, before operating relay *SP*, relay *VT* prepared a path to hold in series with relay *VS* which now operates. Relay *GT* is now operated closing the gate to prevent the operating of any *V* relays by sources other than those which request service at this time. The order of service of gate type lockout circuits is the same with or without the check feature.

Single-Service Gate Preference Lockout

In the panel dial system, line finder switches serve ten groups of 40 subscribers lines each.[5] A control circuit, known as the trip circuit since it controls tripping of the line finder brushes in finding this group, originates a request for service from any of the lines in a group. The line finder action is controlled by a start circuit which is common to 10-trip

Figure 4. Gate preference lockout

Figure 5. Gate check preference lockout

Figure 6. Single-service gate preference lockout

circuits. Line finders are started for only one line group at a time. The associated trip circuit is chosen on a lockout basis among all others requesting service at that time.

The circuit shown in Figure 6 illustrates the lockout circuit which has been used in this application. It is, in effect, a gate type lockout wherein only a single circuit, the preferred one, is admitted behind the gate when being served. Each source is represented in the lockout circuit by a double wound relay *TR*. Two leads *ST*1 and *ST*2 are closed to ground by a source when requesting service. When a source is served, relay *TR* operates by its upper winding through relay *ST* normal. When relay *TR* closes its front contact in the preference chain, relay *ST* operates in series with the lower holding winding of relay *TR* with ground from lead *ST*2. Once relay *ST* operates no other *TR* relays may operate until the operated *TR* relay is released, releasing simultaneously relay *ST*. In this circuit relay *ST* is acting as the gate relay while the preference chain and lower windings of relays *TR* permit only one source request to remain inside the gate.

The circuit as shown favors distinctly the serving of lower numbered circuits. It would thus be possible for two very busy lower numbered circuits to prevent satisfactory service from being given to higher numbered circuits. Therefore it has been the usual practice when employing single-service gate preference lockouts, to provide a form of signal lockout for each request source under the common control of all sources which are requesting service. This prevents further requests from any served source from reaching the preference until all waiting sources have been served at least once.

Preference Changes in Lockout Circuits

Aside from caring for perpetual lockout due to inherent circuit action, lockout circuits are frequently provided with associated circuit arrangements which change the preference order after each usage. Such changes prevent perpetual lockout due to circuit trouble conditions, such as open contacts in the preference chain or troubles in the individual sources being served, which prevent the removal of their request for service. Since a request is for definite services, the lockout circuit may be informed when these services have been rendered so that if the request fails to be released action may be taken to free the lockout circuit from that source. This is sometimes aided by changing the preference after each service. The changing of preference also insures that regardless of position in a lockout chain, waiting requests on the average are served equitably.

There are two methods which have been employed rather extensively to change the preference order in lockout circuits. One of these methods is to reverse the direction of lockout action and service preference on alternate usage of the lockout circuit. Such a scheme applied to the gate-check type of preference lockout circuit is shown in Figure 7. The *W* and *Z* relays comprise a recycling 2-step counter which receives a ground pulse on each operation of the *VT* relay. Relay *W* operates or releases on each ground pulse while relay *Z* operates or releases on the removal of each ground pulse. The ground holding relays *VT*, *VS*, and *SP* are released when each request has been served. Two sets of contact chains wired in opposite directions are provided on the *V* relays. One set is used when the *Z* relay is released, the other when the *Z* relay is operated.

The second method of changing preference is more generic. Here a recycling multistep counter circuit progresses the start of preference to a different point on each service request. The order of progression need not be the same as the preference chain order. Figure 8 shows this type of arrangement where for the sake of simplicity the details of sequence or counter circuit have been omitted.

With some types of lockout there is the disadvantage that, once a trouble condition develops, requests may be served at only half their former rate. By the addition of a signal or line type lockout circuit to each path which provides access to the preference lockout this condition may be eliminated.

Another way in which preference and other chains are guarded to prevent perpetual lockout is to provide two identical lockout circuits, one for regular use and the other for emergencies. When a trouble is detected provision is made for automatically transferring from one lockout circuit to another. This arrangement not only gives regular service in event of trouble but prevents perpetual lockout to

Figure 7. Gate check lockout with preference reversal

Figure 8. Gate lockout with changeable preference start

Figure 9. Gate preference lockout arranged to detect abandoned attempts

Figure 10. Improved single-service gate preference lockout arranged to detect abandoned attempts

a given source due to an open lockout relay winding. An arrangement of this type has been described in detail.[6]

Abandonment of Service Request

In some applications of lockout circuits in common control switching systems, the serving of a request is the start of a comparatively long and complex series of circuit actions by some control circuit. Furthermore the request to the lockout circuit may be the only direct indication of the service request received by the common circuit. A frequent occurrence in telephone switching is the abandonment of calls. It is desirable and sometimes necessary that the lockout circuit be arranged to detect the abandonment of the request without starting the service of a new call before the common circuit has fully restored to normal. In the circuit arrangements thus far discussed abandonment of the call being served would enable the release of the lockout relay and the preference chain would then connect with another call awaiting service. This might cause the common circuit to act falsely for one request on the basis of information received from a previous request. Means may be provided in the lockout circuit for recognizing this abandonment condition and preventing this incorrect action. Otherwise the circuit requesting service must recognize the abandonment condition but prevent its influence on the lockout circuit.

The circuit arrangement shown in Figure 9, applying to the gate-type lockouts, provides an extra preference chain connected to the winding of each lockout relay with an end chain relay. The end chain relay, *AB*, is connected to ground supplied by the common circuit giving service. Relay *AB* is normally not operated. However should a request for service be withdrawn during service, relay *AB* would operate in series with the lockout relay being served to prevent switching preference and to give an indication of the abandonment.

A more recent version of the single-service gate preference circuit with provision for detecting abandonment is shown in Figure 10. In this circuit only one *ST* lead is required per source and a gate relay with a make contact per source is used (Figure 6). This gate relay *GT* is normally operated from ground through relay *AB* normal when the source is ready to serve. When a source requests service, its associated *V* relay operates. The preferred *V* relay, if more than one operates, locks to the ground supplied by the common circuit while relay *AB* operates from the source *ST* lead ground. Relay *AB* in operating operates relay *GTR* which locks to the common control ground operating relay *GT*. Relay *GT* releases after relay *GTR* locks operated. The release of relay *GT* releases the *V* relays of all nonpreferred sources. Relay *AB* is now the only control point in the circuit connected with the preferred source and its premature release indicates abandonment.

As was the case with the single service gate preference circuit shown in Figure 6, means must be added in the application of this circuit to provide for more equitable distribution of service. In a recent application of this circuit in a cross bar system, this was accomplished by employing alone or in combination, two artifices mentioned previously. One of these is the changing of preference after each use by a multistep sequence circuit. The second is the use of a signal lockout per source which prevents further requests until all waiting sources have been served.

Tandem Operation of Lockout Circuits

In the application of the end relay lockout of Figure 1, 48 or more pairs of lockout relays, one for each trunk served by the same operator, were required. By grouping the trunks and providing one or more lockout circuits to determine the group or subgroups to be served and one or more lockout circuits to determine the particular trunk to be served within the group or subgroups the total number of lockout relays required could be reduced. An example of this tandem use of lockout circuits may be found in the crossbar system where as many as 700 lines may be served by one controller.[7] The lines are divided into ten groups of 70 lines each and each group of 70 lines is divided into seven subgroups of ten lines each. With three lockout circuits of 10, 7, and 10 inputs operating in tandem, a process of elimination takes place which permits the lockout serving of any of 700 inputs with 27 lockout relays. Care must be taken to insure that the sources examined at each lockout step are associated with the subgroup of sources locked out in the previous step. The relay saving with tandem operation is secured at the expense of an increase in the total lockout circuit action time required to determine the source to be served.

Conclusion

Relay circuits are used in telephone switching to provide service to competing sources on a one-at-a-time basis. For small numbers of sources, one or two relays per source are required, sometimes in combination with a number of relays common to all sources. Where the number of sources is large they may be

grouped to enable serving by several lockout circuits in combination. Means are sometimes added to the lockout circuit to detect troubles which prevent the serving of some or all sources. Relay type lockouts do not necessarily serve requests in the order of their arrival particularly under heavy load conditions. As a result some sources may be assigned positions where, under given load conditions, they encounter more or less than the average delay. To enable the equitable distribution of delay among all sources under all load conditions, and to mitigate various troubles which may prevent the rendering of service, preference changing means may be provided. Arrangements to detect the abandonment of calls and under such conditions to prevent the premature serving of another request may be required for some applications, particularly when directly rendering service for subscriber calls.

Discussion

Frederick L. Kahn (Automatic Electric Company, Chicago, Ill.): The circuits described in this paper are very simple, but their function in modern high-speed switching systems is most important as they assure the orderly dispatch of calls made in rapid succession by different subscribers who compete for immediate service by equipment units or operators.

Joel is to be complimented on his lucid presentation of this problem and the methods available for control. This will assist all of us in the telephone industry to speed up and improve the process of training young engineers; it is impossible to include such material in the present college curricula.

Many organizations working in the telephone switching field have been faced with the problem of preference lockout circuits in automatic switching system. The automatic (cordless) toll board is one of the situations where an orderly handling of waiting calls is important. Circuits such as described in this paper are being used for this purpose, but in some instances more rigid sequence control has been demanded by traffic operating engineers. For such cases, there have been designed lockout and sequence answering circuits that assure the answering of waiting calls strictly in the order of arrival; that is, first come, first served.

Such circuits are more elaborate and more expensive than the preference lockout circuits shown in this paper. The need for complete sequence control is controversial. As no circuits of this type are included in Joel's paper, I should like to ask whether preference lockout circuits with "sequence of arrival" control are used by the Bell Telephone System; if so, for what type of application?

A. E. Joel, Jr.: In the Bell Telephone System arrangements are available for serving calls to information desks and order turrets in the strict order of arrival. Service of this nature is not provided by preference lockout circuits. Multifunctional circuits consisting of allotting and sequence functions are employed.[1]

Power Distribution and Utilization in a Large Iron Ore Beneficiation Plant

A. F. GETTELMAN
NONMEMBER AIEE

Synopsis: Large iron ore beneficiation plants introduce new problems of distribution and utilization of electric power in the iron mining industry. The selection of voltage levels for generation and main distribution, large and small motors, is based on a study of installed cost system reliability and efficiency. A modern load center system of distribution of a-c and d-c power for a large plant unit is demonstrated.

RESERVES of high grade iron ore in the United States are running out. Some experts estimate that direct shipping ores of 50–65 per cent iron content will last only another eight to ten years. Of course, some ore requirements have been and will continue to be supplied from intermediate ore concentrated in plants using a simple sedimentation process of washing, classifying, and crushing when necessary. However, the low grade taconite ores of the Mesabi range must be concentrated or beneficiated in increasing amounts if we are to maintain our steel production from domestic sources.

Taconite ore occurs in both magnetic and nonmagnetic forms. The taconite to be beneficiated in the plants now being planned is a hard dense rock averaging about 24 per cent iron in the form of magnetite. The iron content is so finely divided that nearly all particles are smaller than 20 mesh. The rock must be crushed in three or four stages and then be ground to a powder so fine that 85 per cent of it is minus 320 mesh. Magnetic separators reduce the burden of grinding in the ball and rod mills and in combination with classifiers and a plentiful supply of water produce a concentrate in the form of a fine black powder. This powder must be sintered or made into hard pellets to be suitable for the blast furnaces. Nearly three tons of iron bearing rock is reduced to one ton concentrate of approximately 64.5 per cent iron.

To utilize the low grade ore, huge beneficiation plants must be built—plants that will require 25,000–30,000 installed horsepower to produce 2,500,000 tons of concentrate annually. The purpose of this paper is to discuss the problems of electric power distribution and utilization in such plants as these.

The importance of the subject can be appreciated when it is considered that 60–75 kilowatt-hours will be required to produce one ton of concentrate from taconite ore. In 1935 the Minnesota ranges produced a ton of iron ore with 3.5 kilowatt-hours of electric power. To produce 2,500,000 tons of concentrate may require as many kilowatt hours as was used to produce 63,000,000 tons of ore in 1945.

While experimental plants of about 200,000 tons annual capacity are being built, the ultimate plants for economical operation must be much larger units. Plans are now under consideration for a beneficiation plant unit with a capacity of 2,500,000 tons of concentrate annually, with ultimate expansion to four units producing 10,000,000 tons. The flow sheet of such a plant unit is shown in Figure 1, and the power requirements are listed in Table I. The approximate connected horsepower for such a plant unit is

Crushing plant—3,500 horsepower
Concentrating plant—18,000 horsepower
Sintering plant—8,000 horsepower

Power for beneficiation plant units with 30,000 connected horsepower is not available at present in the areas of the Mesabi range containing the ore reserves. Generating plants will have to be built near the plant site where conditions are favorable, and the following is based on the typical beneficiation plant with power generation at the plant site. In addition, it also is assumed that the single unit plant will be built and operated as a single unit for some period of time.

Selection of System Voltage Levels

The Table II shows the utilization equipment voltage ratings, generator, and stepdown transformer voltage ratings, and the corresponding nominal system voltages with which we are concerned in a beneficiation plant such as this.

The selection of the proper system voltage for the first plant unit and for future plant units should be on the basis of overall economy. The cost of component parts of the power system including switching equipment, distribution channels, transformers, and even the rating of motors must be taken into consideration.

The chart in Figure 2 shows the selection of the main generation and distribution level for new plants based on good engineering practice. For a plant with 30,000 horsepower installed and generation at the plant site, 13,800 volts is the preferred level for the main generation and distribution.

Selection of Motor Voltages

The horsepower ratings of motors in a modern beneficiation plant range from 1 horsepower induction motors on feeders and separators to large synchronous motors on rod and ball mills, and also on fans for a sintering plant. Plans available today on these plants do not indicate the use of motors over 1,000 horsepower.

Motors with 440-volt rating have been standard in the mining industry for the lower horsepower range, and will be used in the beneficiation plants. Many studies

Paper 48-313, recommended by the AIEE mining and metal industry committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted July 29, 1948; made available for printing September 15, 1948.

A. F. GETTELMAN is with the General Electric Company, Minneapolis, Minn.

Figure 1. Flow sheet for a typical large beneficiation plant unit

Figure 2 (upper right). Selection of main generation and distribution voltage in terms of mill electrical capacity

Figure 3 (lower right). Cost of motors and control versus horsepower rating of motors

have shown that a 220–230 volt rating would not be economical due to the increased cost of feeders, control, and switching equipment. Motors of 550-volt rating have been used in other industries such as some paper or textile mills, but new plants are using 440-volt motors due to their greater availability.

In the higher horsepower range up to 1,000 horsepower, 2,300-volt or 4,000-volt motors will be used. To determine what part of the horsepower range will use 440-volt motors, the over-all economy must be considered, taking into account the costs of motors and their controls and transformer capacity, since all motors will require installed transformer capacity with a main distribution voltage of 13,800 volts.

Transformer costs in dollars per kilowatt-ampere decrease as the transformer rating increases. However, as the transformer rating increases the fault duty in the low voltage bus increases, requiring larger and more costly circuit breakers.

For the 440-volt motors, the optimum size of unit substations ranges from 500 to 1,500 kva. Where load concentrations are high, as in the concentration plant, studies indicate the use of 1,000-kva units.

For the 2,300-volt or 4,000-volt motors in the higher horsepower range, larger transformer units are warranted, since short-circuit interrupting levels up to 150,000 kva at 2,400 volts, and 250,000 kva at 4,160 volts may be used with good economy. For the 2,300- or 4,000-volt motors, unit substation transformers of 5,000 or 7,500 kva respectively will provide the best over-all economy, taking into account, location of load, circuit arrangement, and so forth. In the circuit arrangement as shown in Figure 4, the use of 6,000-kva transformer units is indicated.

To compare the costs of motors and controls, the curves in Figure 3 have been drawn, based on standard 1,200-rpm induction motors and full voltage starting. At 200 horsepower a comparison of the 440-volt and the 2,300-volt motor and control shows an increased cost of approximately four dollars per horsepower at 2,300 volts. However, the investment cost in transformer substation capacity

for the 2,300-volt motor will be from four to six dollars less, depending on the load factor used. From this comparison it is apparent that motors up to about 200 horsepower can be served more economically at 440 volts.

Figure 3 does not show the comparison of synchronous motors and controls. However, there is less price differential between 440-volt and 2,300-volt synchronous motors and control than there is between induction motors and control at these voltages. The result will be to bring the curves closer together in Figure 3 and lower the maximum horsepower rating to be used at 440 volts.

Based on this division of motor voltage ratings, the power requirements for the plant are divided approximately as follows:

A—Crushing Plant

1. Induction motors over 200 horsepower for driving crushers and large conveyor belts.
2. Induction motors under 200 horsepower for driving conveyor belts, feeders, screens, and dust collectors.
3. Miscellaneous power for lighting, crane repair shops, and so forth.

B—Concentrating Plant

1. Synchronous motors over 200 horsepower for driving ball mills and rod mills.
2. Induction motors over 200 horsepower for driving pumps.
3. Induction motors under 200 horsepower for driving conveyors, classifiers, magnetic separators, pumps, and so forth.
4. D-c power for:
   (a) Excitation of magnetic separators.
   (b) Excitation of magnetizing coils.
   (c) Excitation of synchronous motors.
   (d) D-c motors driving adjustable speed feeders to the grinding mill.
5. Miscellaneous power including lighting repair shops, cranes, demagnetizing coils, and so forth.

Power Circuit for Synchronous Motors on Rod and Ball Mills

The rod and ball mills (Figure 1 flow sheet) will be driven by slow speed synchronous motors in horsepower ratings between 450 and 700, using full voltage starting, as is the practice in ore treating

Utilization Equipment Voltage Rating	Generator Transformer No Load Voltage Rating	Nominal System Voltage Class
440 or 460	480	460
2,300	2,400	2,400
4,000	4,160	4,160
13,200	13,200 to 14,400	13,800

Figure 4. Power distribution system for typical large beneficiation plant unit

mills now in operation. The voltage rating of these motors can be 2,300 or 4,000. A study must be made of all factors, including cost of switching equipment, motors, controls and feeders to determine the most economical voltage rating of these motors.

A mill unit with 24 synchronous motors of 500 to 700 horsepower will require a number of small transformers and a multiplicity of switching equipment if a selective bus arrangement is used and the motor circuits are to be limited to a low interrupting level for short-circuit duty. With a low interrupting level, a large voltage drop occurs when starting a large synchronous motor. Since motor torque is proportional to the square of the voltage, it therefore is reduced considerably. The high torques required for synchronous motors used on ball and rod mills represent a substantial part of the first cost of these motors.

For example, if the interrupting level and short circuit is limited to 25,000 kva, then a 600-horsepower motor with 600 per cent locked rotor current and power factor of 40 per cent would have only $86^1/_2$ per cent voltage on starting, and this will produce only 75 per cent of the full voltage starting torque on the motor.

Full voltage starting, using electrically operated power oil circuit breakers in metalclad switchgear, has been the practice on the ball and rod mill synchronous motors. With the development of the modern high-voltage air circuit breakers of the magnie-blast type, the use of oil circuit breakers can be eliminated. The air circuit breakers will reduce contact maintenance when used in the motor starting units.

Another type of motor starting control that has found widespread use in other industries, such as the rubber and paper mills, is one utilizing modern high voltage air break contactors with short circuit protection provided by means of high interrupting capacity current-limiting fuses. These air break contactors have been used on severe operating cycles and are suited particularly for jogging operations where a mill is being rotated to a given position.

The current-limiting power fuses are co-ordinated with the motor so that they will operate only under short-circuit conditions and will not blow unnecessarily on motor starting and stalled rotor currents. The current-limiting action of the fuse reduces the fault damage by limiting the fault current.

The maximum economical ratings for power circuit breaker are shown in Table III.

High interrupting capacity motor starters with current-limiting fuses, also follow the same limits as curcuit breakers, that is, system fault duties of 150,000 kva at 2,400 volts and 250,000 kva at 4,160 volts.

From Table III it will be noted that a 600-ampere curcuit breaker is adequate to interrupt 150,000 kva at 4,160 volt, whereas a 1,200-ampere circuit breaker is required to interrupt 150,000 kva at 2,400 volts.

The power circuit breaker not only must be capable of interrupting the fault current at the time of short circuit, but also must withstand the high mechanical forces produced by the initial first half cycle of short-circuit current. There is also a limit to the current a power circuit breaker will interrupt regardless of voltage, and it also may not be able to interrupt its rated kilovolt-amperes at all voltages.

At 4,160 volts, the power circuit breakers and current-limiting fuses may be applied up to their maximum interrupting rating. A 600-ampere power circuit breaker at 4,160 volts will carry 1.73 times the kilovolt-amperes that it will at 2,400 volts. The installed cost of cable is approximately inversely proportional to the system voltage or 73 per cent more for the 2,400-volt system than for the 4,160-volt system.

Figure 4 shows a proposed power distribution system for a modern beneficiation plant using a flow sheet similar to Figure 1. A modern load center system of power distribution is used for the power requirements for both the high voltage mill motors and also the low voltage motors.

The synchronous motors on the ball and rod mills have a 4,000-volt rating. Power is supplied to these motors from master unit substations with 3-phase oil-filled transformers equipped with fans for increased supplementary rating. Each unit substation transformer has a cable junction entrance for the 13.8-kv cable from the generating plant. Oil-filled transformers are indicated as the concentrator plant construction usually will permit the transformers to be located along the outside wall of the building at locations convenient to the motor loads they serve.

Where the control room can be located along the outer wall of the concentrator plant, convenient to the transformers, a metal-enclosed bus duct is a preferred means of connecting the transformer to the metalclad switchgear. This arrangement provides a completely enclosed system from the power station to the motor. The space requirement is much less than for the older type substations using single-phase transformer banks and open bus work and disconnect switches. A high degree of safety and reliability is obtained, and switching is accomplished safely and quickly with circuit breakers of full interrupting capacity.

Normally, the substations would be operated separately. With the tie bus as shown, in the event of a transformer or a feed failure, the bus sections can be operated from the remaining three substations in parallel without exceeding the circuit breaker or fuse interrupting rating.

The 13.8/4.16-kv master unit substations consist of a transformer, metalclad switchgear which contains the tie and feeder circuit breakers, and the motor control sections using current-limiting fuse starters.

To permit using the full 250,000-kva interrupting rating of the power circuit breakers and current-limiting fuses in the motor controls when the tie circuits are closed, 4,160 volts was selected. To use 2,300-volt motors in a circuit as in Figure 4, the short-circuit interrupting level must be limited to 150,000 kva, and so will require the use of current-limiting reactor units in each of the tie circuits. A study of comparative costs shows that the savings at 2,400 volts in costs of motors and control is offset by the additional cost of the feeders, power circuit breakers, and reactor units in the switchgear.

The use of motor controls with current-limiting fuses of high interrupting capacity represents a considerably lower investment than motor controls using power circuit breakers at the high interrupting levels.

In choosing a circuit arrangement such as that shown in Figure 4, a balance between the desired reliability and the installed cost of the system must be considered. With the large capital investment in the plant and with 3-shift operation of the concentrator plant, continuous power supply is essential.

Grounding of High-Voltage Mill Circuits

The established practice has been to operate the present mills with the 2,400-volt motor circuits ungrounded; the thought being that with the system left ungrounded no loads would be lost and the system operated until some future time when the ground could be removed.

Aside from having to isolate each circuit to find the ground, there are other disadvantages of an ungrounded system.

The occurrence of a ground on one phase overstresses the windings of all machines while the ground is on. Switching surges and arcing grounds can produce serious overvoltages up to six times normal. As a result, flashovers that are difficult to explain are found at locations remote from the actual ground fault.

In Fig. 4, the neutral of the Y-connected 4,160-volt winding on each 13,800/4,160-volt substation unit is grounded through a current-limiting resistor. This resistor can be mounted in a protective metal enclosure on the transformer unit itself. Ground fault relaying is provided on all feeder circuits, and phase protection on the motor starters.

D-C Excitation of Synchronous Motors on Ball and Rod Mills

The use of separate motor-generator sets rather than direct connected or V-belt-connected exciters saves valuable space in the mill area. The motor-generator sets can be located under better operating conditions in the control room. If an individual motor-generator set is furnished for each motor, a large number of small units are required. If, on the other hand, several large motor-generator sets are used for excitation of all the synchronous motors, spare capacity and d-c distribution are important factors. The a-c motors on the motor-generator sets can be supplied best from the 4,160-volt mill motor circuits to provide the desired reliability.

In the arrangement as shown in Figure 4, a motor-generator set exciter is provided for each of the mill sections. Each mill section consists of two synchronous motors driving ball mills and one synchronous motor driving a rod mill. A spare set can be connected to any section and provides reliability with a minimum of equipment.

The exciter sets are supplied from two 4,160/480 load center units using noninflammable liquid-cooled transformers. Control for the exciter set motors may be incorporated conveniently in the secondary switching section of the load center unit. Additional 460-volt power for lighting, control battery charging and for small feeder motors on this side of the mill also can be taken from these unit substations.

Power Circuits for Low-Voltage Motors

Load center unit substations using askarel-filled transformers are available for 13.8-kv circuits and will provide the most satisfactory and economical distribution of 460-volt power. They can be located in the control room adjacent to the 440-volt motor load. With magnetic ore dust and moisture present, the use of air-cooled transformers would require special attention. Studies that have been made indicate that for the 460-volt concentrator power, units of 1,000-kva capacity will be the most economical. The use of two 13.8-kv feeders with several unit substations on each feeder and a secondary selective system is preferable to a primary selective system which would require 13.8-kv switching equipment.

Table III

Circuit Breaker Ampere Rating	Interrupting Rating, Kva
	2,400-volt service
600	100,000
1,200	150,000
	4,160-volt service
600	150,000
1,200	250,000

440-Volt Motor Control Centers

The concentration of 440-volt motors in the mill is such as to provide an excellent application of modern control centers, incorporating the short-circuit and thermal overload protection in each starter for the individual motors. With control centers located in the control room apart from the classifiers and pumps, the control equipment can be maintained more satisfactorily, with greater accessibility and with space saved in the mill.

Magnetic Separators

From the flow sheet (Figure 1) it will be noted that 64 single drum "roughing" magnetic separators are used after the rod mills and 48 single drum "finishing" magnetic separators are used after the hydro separators. Typical power requirements for the magnets in these separators are shown in Table IV.

Table IV

	Pick Up Pair Numbers 1 and 2	Tailings Pair Numbers 3 and 4	Concentrate Pair Numbers 5 and 6
48-inch drum rougher separator	3.3 kw max	4.0 kw max. Operate at 2.8 kw	4.0 kw max Operate at 2.8 kw
48-inch drum finisher separator	3.3 kw max	4.0 kw max. Operate at 3.1 kw	4.0 kw max Operate at 3.1 kw

Based on the requirements given in Talbe IV, 64 roughing and 48 finishing magnetic separators would require approximately 1,000 kw of d-c power for magnetic excitation. While the use of 125 volts direct current may be preferred in the winding of the magnetic separator coils, 230 volt d-c separators are standard and there is comparatively little difference in price. Therefore, a 250-volt d-c supply system is recommended as it will provide the lowest cost distribution system including cables, switches, and power supply equipment.

If the magnetic separators can be wound for the approximate field strength required in actual operation, then very little power loss occurs in the rheostats on the tailings and concentrate magnets where adjustment of operating strength is required. On this basis, the most economical power supply is a 250-volt d-c rectifier of the sealed tube ignitron type.

Where a wide range of magnet strength may be required and the operating losses in the rheostats of the magnetic separator are considerable, the use of multiunit motor-generator sets with separate excitation should be considered for over-all economy. The magnetic separators in any one of the eight mill sections would be adjusted as a unit, and the same voltage impressed on all tailings or concentrate coils in a roughing or finishing section from an adjustable-voltage generator.

The driving motors for the motor-generator sets will be of sufficient size so that they can be operated directly from the mill circuits which supply the synchronous motors on the ball and rod mills. Since there will be available with the high torque synchronous motors on the rod and ball mills an excess of leading reactive kilowatt-amperes, synchronous motors are not essential on these motor-generator sets.

The sealed tube ignitron rectifier will consist of a transformer section, a rectifier section, and a d-c distribution section. The primary low-voltage air curcuit breaker will be located in the unit substation supplying power to the rectifier. These rectifiers could be supplied from either the 13.8-kv circuits, 4,160-volt, or the 480-volt circuit. An over-all study of the cost of feeders, switching equipment, and transformer capacity must be made in each case to determine the most economical installation. In Figure 4, four 300-kw sealed tube ignitron rectifiers are shown. Each rectifier unit furnishes

the d-c power requirements for two of the eight mill sections. The rectifiers are operated from the 480-volt unit substations which are located along side the rectifiers in the same control room.

The d-c distribution section in each rectifier will provide the protective circuit breakers for supplying two sections of magnetic separators. These circuit breakers should be of the type used for field circuits of large a-c generators and should have a discharge contact for the highly inductive magnetic separator coils. They can also be electrically operated for remote control from the operating floor. Ground detector lamps on the panels will be provided for indicating grounds in the magnet coils.

Crushing Plant Power Distribution

The location of the crushing plant is a factor in the selection of the circuit arrangement to be used. In Figure 4, it is assumed that the entire crushing plant is located adjacent to the mill.

The power supply to the crushing plant must have the same degree of reliability as for the concentrator plant. In Figure 4, the crushing plant power is supplied at 4,160 volts from one of the 3-phase unit substation transformers. The large crusher motors are supplied directly at 4,160 volts and the smaller motors below 200 horsepower are supplied at 460 volts from a load center unit substation.

When a central crushing plant first is built, with capacity for several mill units, then the power requirements and the load locations may be such that a 13.8-kv circuit to the crushing plant is more desirable.

Motors and Control for Crushing Plant

High-voltage air break contactors have been designed for severe duty cycles such as in mine hoist service and will require a minimum of maintenance in the operation of large crusher motors where frequent starting and stopping and reversing is encountered. In the past, electrically operated oil circuit breakers have been used for this service. However, under frequent operations, the maintenance of latching mechanisms and circuit breaker contacts is a considerable item.

The large gyratory crushers such as the 60-inch size will require two motors of the motors of the wound rotor type, each motor driving the main gear on the crusher through its own pinion. The two motor stator windings can be connected in parallel to one set of reversing air break contactors. Four-pole secondary contactors will provide separate balanced accelerating steps for the rotor circuits of the two motors. Definite time limit acceleration is provided by means of magnetic time delay relays.

Gyratory crushers of the 24-inch size also will be driven by wound rotor motors and will use a control similar to that for the 60-inch crusher except designed for a single motor.

The short head crushers are usually driven by squirrel cage induction motors. Full voltage starters using air break contactors are shown for these motors.

All control units with air break contactors will be protected by current-limiting fuses of 250,000 kva interrupting capacity at 4,160 volts.

Conveyor Belts

A large number of conveyor belts of varying width, length, speeds and lift are required to transport the ore through the various stages of crushing, grinding and concentrating. For the smaller belts, requiring 100 horsepower or less to drive excellent results have been obtained with high torque squirrel-cage induction motors and full voltage starting. The high starting torque motors, such as type *KG*, have approximately 200 per cent starting and 200 per cent pull-out torque, which is usually ample for starting the belt under all operating conditions. The use of normal torque motors often results in overmotoring the drive with resulting higher belt stresses.

Conveyors requiring motors of 200–300 horsepower usually are equipped with belts operating under high stresses. To limit the starting and accelerating torque on these belts, wound rotor motors with secondary control providing automatic time limit acceleration are recommended.

On extremely large belts operating at high stresses, where starting and accelerating torques must be held to a minimum, a large number of accelerating contactors would be required. A number of installations are now in successful operation using a standard 13-point motor-driven drum controller to provide definite time limit acceleration in place of the contactors.

A magnetic time relay provides a means of adjusting the time interval between the first several accelerating points. Control circuit cams on the drum controller provide for sequence starting of the next unit, or sequence starting between two motors operating in tandem on the same belt, and for the release of hold-back devices that may be used. The controller is interlocked with the primary starting switch so as to start only when on the first controller point.

Agglomerating Plant

To complete the picture of the beneficiation plant, a brief review is in order, of the two methods of agglomerating the concentrate, namely, sintering and pelletizing.

Sinter Plant

In the sintering process, the powdered concentrate is mixed with 4–6 per cent pulverized coke or coal, and the mixture distributed on a long slow moving chain grate.

The mixture is ignited and combustion is maintained by large induced draft fans connected to suction boxes under the grate. After leaving the grate, a water quench produces a suitable furnace product in the form of clinker.

The power supply for a sintering plant has been included in Figure 4. Large synchronous motors on the fans constitute the major part of the load. In the proposed plan for one large plant, these motors are rated 900 horsepower. The motors must be 4,000 volts in ratings above 700 horsepower, 0.8 power factor for full voltage starters using current-limiting fuses.

The 460-volt load center power distribution system is similar to that shown for the concentrator plant.

The use of a tie circuit also on the 4,160-volt sinter plant thus provides power for the sinter plant on loss of a feeder or transformer unit. Three transformer units may be operated in parallel if necessary for carrying the entire load without exceeding the 250,000-kva interrupting level.

Pelletizing Plant

Experimental work is being carried on and pilot plants now are being built to produce in commercial quantities, a furnace product from the powdered concentrate by means of the pelletizing process developed in the Minnesota Mines Experiment Station. This process holds great promise of reducing the cost over that now obtained in ore concentrating plants using the sintering process.

The pelletizing process consists of mixing 1.25–1.5 per cent finely pulverized coal with the powdered concentrate along with the proper moisture and balling up this mixture in a revolving drum.

The wet balls, 1/2 inch to $1^1/_4$ inch in size, then are charged in a vertical shaft furnace where the temperature is maintained slightly under the fusion point of the concentrate.

No complete data are as yet available on the power requirements for large pelletizing plant units. From available data it appears that the maximum motor horsepower ratings will be within the limits of 460-volt distribution. On this basis, the power distribution would consist of load center unit substations 13,800/480 volts with a primary arrangement and secondary selective system as in Figure 4, for the 460-volt power distribution in the concentrator plant.

Lighting Distribution

A combined lighting and power system will provide low first cost and excellent over-all service reliability in the plant areas. In this system, small dry-type transformers are connected to 460-volt feeders on the load center unit substations to provide the lighting power requirements. The use of separate transformer substations and feeders for lighting, especially in buildings such as the concentrator which may exceed 600 feet in length, would result in considerably higher first cost and less service reliability.

In areas remote from the mill where lighting and small motor loads are encountered, such as large offices and mill laboratories, 208Y/120 volt service is advantageous since both single-phase and 3-phase power is available for both lighting and small motors.

Push Button Switching in Telegraph Systems

R. F. BLANCHARD
NONMEMBER AIEE

W. B. BLANTON
NONMEMBER AIEE

PAPERS presented before the Institute in previous years have described broadly the methods by which telegraph communications are handled between patrons located in widely separated points, and in particular have outlined the system employed in the more modern offices for relaying messages between incoming and outgoing circuits. Because consecutive messages arriving on an incoming circuit are usually directed to different and widely separated destinations, one of the most costly and time-consuming phases of telegraph operations has been the separation of a continuous incoming stream of telegraph messages into its separate components, sorting out these separate messages and then starting them out again, each to its own separate destination.

The modern system of performing this complicated relay operation, the reperforator switching system, has been described in previous papers[1,2] in its original form which employed the plug and jack type of switching. A more recently developed type of reperforator switching system is that utilizing push button control, which Western Union installed in its Philadelphia and Cincinnati offices in 1947. This system employs the same fundamentals of reperforator-switching as the original system, but the method of effecting the intraoffice connection is quite different. A special adaptation of this system for private line telegraph systems was described in a recent paper.[3] A more highly developed form of push-button reperforator switching suitable to the needs of commercial telegraph offices is described in this paper. Figure 1 shows one of the push-button switching aisles in the Philadelphia office.

Principal Elements of a Reperforator Switching Unit

A switching system may be considered as consisting of three principal parts:

1. Line receiving printer-perforators to receive line signals and record them in the form of printed and perforated tape.
2. Line sending transmitters to transmit line signals from a perforated tape.
3. Intraoffice switching facilities which includes transmitting and perforating apparatus for distributing signals from the received printer perforator tapes to the various line transmitters, each of which serves one channel of an individual outgoing circuit.

There is little of a technical nature that is new in items (1) and (2), except the printer-perforator used at line receiving positions. Machines for automatically perforating tape, from received signals, and for automatically retransmitting equivalent signals from such tape have been used in the telegraph industry for many years. The printer-perforator, however, not only perforates the code selection characters in a paper tape, but also prints the corresponding characters on the same tape in order to facilitate reading by switching clerks. The heart of a reperforator-switching system lies in the intraoffice switching facilities to which the major part of this paper will be devoted.

Line Receiving Positions

A line receiving position is equipped with a printer-perforator, and also with its associated portion of the intraoffice switching apparatus. Such a position has a printer-perforator which receives from a line circuit, an intraoffice transmitter through which the tape produced by the printer-perforator flows (one message at a time with each switching operation), and a tape accumulator mounted between the printer-perforator and the transmitter, into which the tape from the printer-perforator feeds, and from which the tape is withdrawn as the transmitter functions. Three heavily loaded, or five lightly loaded, receiving positions are mounted adjacent to a push-button switching turret. Figure 2 shows a 5-position turret.

Line Transmitting Positions

Transmitting positions are equipped with line sending apparatus and associated intraoffice switching apparatus. In addition to the line transmitter which is continuously connected to its transmitting circuit, there is a reperforator (non-printing) which receives signals over an intraoffice circuit from the various intraoffice transmitters, a tape accumulator like the one described for receiving positions and an automatic numbering machine. Tape from this intraoffice reperforator flows continuously through the line transmitter as long as there is tape on hand to transmit (Figure 3).

Intraoffice Switching Operation

When a telegram is received at a line receiving position, a switching clerk notes the destination of the message as printed on the tape produced by the printer-perforator (Figure 4) and determines from memory or from a route chart the circuit over which it should be retransmitted. The clerk then depresses an "initiate" push-button which is located adjacent to and on the same shelf with the intraoffice transmitter, which is associated with that tape

Paper 48-317, recommended by the AIEE communications committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted August 4, 1948; made available for printing September 13, 1948.

R. F. BLANCHARD and W. B. BLANTON are both with the Western Union Telegraph Company, New York, N. Y.

Figure 1. A push-button switching aisle at Philadelphia, with type 36-A chadless tape printer-perforators

Figure 2. A 5-position switching turret, with type 36-A chadless tape printer-perforators

(Figure 5). The initiate push-button conditions that transmitter for the switching operation. The "destination" push-button in the switching turret corresponding to the desired outgoing circuit is then depressed. The push-buttons in the switching turret control rotary switches, through which a potential connection is established between the conditioned transmitter and the selected intraoffice circuit. This potential connection is not converted into an actual connection, until a transmitter allotter has functioned to test a path of that intra-office circuit and has found it to be idle. Then the actual connection is established through that path of the intraoffice circuit into a reperforator associated with the desired transmitting circuit, either directly in the case of a single-channel circuit, or through the functioning of "transmitter finder" and "load distributor" switches in the case of multi-channel circuits to the desired destination.

When an actual intraoffice connection has been established between a transmitter at a line receiving position and a reperforator at a line transmitting position the intraoffice circuit is immediately seized by an automatic numbering machine which transmits into the intraoffice reperforator the correct message sequence number for that sending channel. After the operation of the automatic numbering machine, the intraoffice transmitter sends its telegram. All telegrams are terminated with a special end-of-message signal, consisting of two periods(..) which causes the intraoffice transmitter to stop and to be disconnected from the intraoffice circuit, thereby clearing that circuit for use by any other intraoffice transmitter which may be seeking a connection to it. The message has now been transferred from the printer-perforator tape of the receiving position to the reperforator tape at the sending circuit terminal. As described previously retransmission of the message to the outgoing circuit is accomplished by this perforated tape automatically flowing through the line transmitter.

Intraoffice Switching Facilities

Circuits. Nine conductors are involved in establishing an intraoffice connection. Three of the conductors perform functions required in establishing the connection, in providing supervisory signals, and in disconnecting, while the other six conductors are used in transmission. The use of six conductors, one of which is used for the transmitter step pulse, makes possible the simultaneous transmission of all five of the code pulses for one character. This enables the intraoffice apparatus to be operated reliably at a transmission speed of 15 characters per second (equivalent to 150 words per minute) with little maintenance attention.

Intraoffice circuits differ depending upon whether they serve an outgoing circuit which has but a single channel or a circuit which has several channels.

Figure 6 is a block diagram which shows two types of intraoffice switching circuits, one for a single-channel circuit designated as *AB*, and the other for a 3-channel circuit designated as *BC*.

Figure 3. A transmitting position with intra-office reperforator and line transmitter

Figure 4. A section of printer-perforator tape, from a 23-A chad-tape type printer-perforator

Figure 5. A receiving position with line printer-perforator of the 23-A chad-tape type, and intraoffice transmitter

Figure 7. Impulse unit sub-base equipped with one impulse unit

The intraoffice reperforator shown on the single sending channel of circuit *AB* terminates an intraoffice circuit that provides only one path for the whole office over which the intraoffice transmitters can reach the *AB* sending position. If two or more intraoffice transmitters are switched to such an intraoffice circuit simultaneously or at approximately the same time, the transmitter allotter, to be described later, will function to permit only one transmitter at a time to receive an actual electric connection while all other transmitters are held in a waiting condition with potential connections.

Where there are two or more channels for a sending circuit, the intraoffice circuit is on a multipath basis. Generally 25 or less paths are provided. Each path, shared by a relatively small group of intraoffice transmitters, terminates in a group of transmitter-finder switches (Figure 6), which are associated with the channels of the sending circuit. These transmitter-finder switches function to connect any one of the intraoffice paths serving that circuit to any one of the channels. If two or more intraoffice transmitters have potential connections at the same time to the same path of an intraoffice circuit, the transmitter allotter functions to permit only one of these transmitters at a time to seize this path. When an intraoffice transmitter has seized a path, the transmitter finder switch of an idle channel will function to complete an actual connection between the intraoffice transmitter and this sending channel position. Therefore, in the case of a 3-channel circuit such as *BC*, three intraoffice transmitters, (if each has access to a different intraoffice path) may send simultaneously into the three intraoffice reperforators which serve the three channels of the circuit *BC*.

A load distributor, common to all of the channels of a multichannel circuit is provided to distribute as evenly as possible, the messages into each of the channels of a multichannel circuit. For example, in the case of circuit *BC* in Figure 6, the load distributor would direct the first message to channel A, the second to channel B, the third to channel C, the fourth to A, and so on, except that when a channel is found busy, the load distributor will by-pass that channel and direct the message to the next idle channel.

Impulse Unit. An impulse unit furnishes the five selection, the step, and the punch pulses for transmitting characters into the reperforator. It consists of a constantly rotating shaft equipped with cams and co-operating contacts, Figure 7. Each cam has two lobes. In each revolution, the co-operating contacts are closed twice, the time and length of closure being determined by the position and length of the lobes. One character is transmitted per half revolution, therefore for 15 characters per second (150 words per minute) the impulse unit is operated at $7^1/_2$ revolutions per second. The timing chart of the closure time for the contacts during the transmission of one character in one-fifteenth of a second ($0.066^2/_3$ second) is shown in the upper right hand corner of Figure 8.

Transmission of the code characters in the tape as it passes through a transmitter is accomplished in the following manner. (See Figure 8.) The step pulse from the impulse unit energizes the step magnet of the transmitter. The operation of the step magnet armature

Figure 6. Switching to single-channel and multichannel circuits

Figure 9. Intraoffice transmission

pulls the feeler pins down and causes their co-operating tongues to move to the spacing bus bar and steps the tape forward to the next character. At the end of the step pulse, the step magnet de-energizes and releases the feeler pins. Each feeler pin that encounters a hole in the tape will project through that hole and its co-operating tongue contact will move to the marking bus bar and thus apply a ground on the associated selection pulse conductor for a marking signal. Each feeler pin that encounters no hole in the tape will be restrained by the tape and its co-operating tongue contact will remain on the spacing bus bar which is ungrounded and thus the associated selection pulse conductor is set up for a spacing signal. The momentary closure of the five selection pulse contacts of the impulse unit will cause a momentary flow of current through the intraoffice reperforator selection magnets that are included in the conductors that are grounded at the intraoffice transmitter. While the reperforator is perforating a received character code, in response to the punch pulse from the impulse unit, the step pulse causes the transmitter to advance its tape to the next character and sets up its feeler pins to correspond to the code combination of that character.

Automatic Numbering Machine

It is an old established practice in telegraphy to number consecutively all telegrams transmitted over a circuit. Number sheets are used at the receiving ends of circuits to check the sequence number of each received telegram. This insures proper reception and prevents duplication of telegrams. In manual operation, a transmitting operator marks on each telegram with a pencil, or with a number stamp, the number under which that message is sent. Therefore, whenever circumstances necessitate doing so, the transmitting office can locate each and every telegram by the number under which it was sent. This is important, since the receiving office may have no record of having received a certain number, or numbers, and would have no means of describing to the transmitting office the omission of a number.

In reperforator-switching operation, these message sequence numbers are automatically transmitted into an intra-office reperforator ahead of each message by an automatic numbering machine. This operation takes place just prior to the transmission of a message by an intraoffice transmitter. Thus, each message and its associated sequence number appear in the same tape at the sending position and all telegrams may be located by their numbers in the same way as described for manual operation.

The automatic numbering machine is a form of transmitter that sends a series of predetermined characters (Figure 9). It functions in a way somewhat similar to a tape transmitter. Whereas the tape transmitter determines the code combination that will be transmitted by feeler pins "feeling" for the holes in perforated tape, the automatic numbering machine has the code combinations for its predetermined characters set up by means of studs in rotating drums. The studs actuate contacts connected to the selection pulse conductors; the presence of a

stud actuates its co-operating contact to apply a ground for a marking signal; the absence of a stud leaves its co-operating contacts open; therefore no ground is applied and a spacing signal is transmitted.

Transmission from an automatic numbering machine into an intraoffice reperforator is accomplished by selection, punch and step pulses from the impulse unit, in the same manner as previously described for the intraoffice transmitter.

Transmitter Allotter

When a potential connection is set up between an intraoffice transmitter and an intraoffice circuit, a circuit is established from the intraoffice transmitter to its associated contact on the transmitter allotter. The latter has 188 contacts arranged in a circle (Figure 10). Inside of the circle is a constantly rotating brush arm that connects ground to the 188 contacts one at a time. This particular allotter makes one revolution every $3^3/_4$ seconds. Each intraoffice transmitter circuit is connected to an individual contact on the allotter. Thus every transmitter waiting to seize an intraoffice path has a momentary ground applied to its circuit once every $3^3/_4$ seconds.

When the transmitter allotter applies ground to the transmitter circuit, a pulse of current will flow if the path of the intraoffice circuit is idle. The flow of current causes the transmitter to seize the intraoffice circuit path and immediately "busies" the path to all other transmitters.

If a second transmitter is endeavoring to seize a busy intraoffice path no current will flow when the transmitter allotter applies ground to the circuit of this second transmitter. Thus the second transmitter cannot seize the intraoffice path until the first transmitter has completed transmission of its message.

When that happens, the next time the transmitter allotter tests through the circuit of the second transmitter, a current flow will result and the second transmitter will seize that intraoffice circuit path.

When an intraoffice transmitter seizes the intraoffice circuit path of a single channel sending circuit, it immediately obtains an actual connection to the intraoffice reperforator on the sending position. However, in the case of multichannel sending circuits, the seizure of any one of the several intraoffice circuit paths sets up a calling condition and the actual connection to an idle sending position is completed by the operation of the load distributor and a transmitter finder switch.

Figure 9. Automatic numbering machine

Push-Button Switching Turrets

As previously indicated, each switching turret serves three or five intraoffice transmitters. The circuit arrangements are so interlocked that only one transmitter of the group of three or five transmitters served by the same turret can be conditioned for a switching operation prior to the act of depressing a turret push-button. This prevents inadvertently conditioning two transmitters at the same time and then connecting the first transmitter to the destination intended for the second transmitter or vice versa.

An "initiate" push-button is associated with each intraoffice transmitter. Momentarily depressing the initiate button of any one of the three or five transmitters served by one turret will condition that particular transmitter circuit through an arrangement of relays so that it will be the next transmitter at that turret to be switched when one of the destination push-buttons in the turret is depressed.

Only one push-button is provided in each turret for each destination. If two or more intraoffice transmitters at the same turret have messages for the same destination, for example Chicago, the switching clerk would depress the "initiate" push-button of one of the transmitters and then depress the Chicago "destination" push-button in the turret. Then the clerk would depress the "initiate" push-button of another transmitter and again depress the Chicago "destination" push-button in the turret. The same procedure would be followed for other transmitters having Chicago messages. These potential connections to the Chicago sending position or positions will be automatically converted to actual connections by the operation of the transmitter allotter, transmitter finders, and load distributor.

Rotary Switches

The rotary switches which constitute the medium for making the connection between the intraoffice transmitters and the intraoffice circuits, have a rotor, comprising a 10-arm wiper assembly, which can be stepped to any one of 25 positions. The stator portion of these switches is equipped with 10 contacts at each of 25 positions. Figure 11 shows two types of rotary switches which operate similarly although different in mechanical construction. Both types are used interchangeably in push-button switching.

The nine conductors of an intraoffice transmitter circuit are connected to nine of the wiper arms of the rotor of a rotary switch. When the rotor is stepped to any one of 25 positions on the rotary switch, the 10-wiper arms make contact with the ten stator contacts at that position. The nine conductors of intraoffice circuits are connected to nine stator contacts on one of the 25 positions of a rotary switch. The tenth stator contact of each of these positions is connected to one of the push-buttons in the switching turret.

Depressing any one of the destination push-buttons in the switching turret will put a "marking condition" on the tenth contact of the rotary switch at the position where the desired intraoffice circuit is connected. The rotor of the rotary switch, by the action of the electromagnet, the stepping pawl, and ratchet wheel, will self-step until it finds this marked condition on the tenth contact. The rotor will then come to rest at that

Figure 10. Transmitter allotter

position on the switch. This connects the nine conductors of the intraoffice transmitter to the nine conductors of the intraoffice circuit through the rotor and stator contacts on nine levels of the rotary switch.

When a turret push-button is depressed, it prepares two circuits, one for actuating the step-magnet and one for marking the position of the rotary switch contact bank where the rotating contacts, termed "wipers", are to stop stepping. The circuit through one pair of contacts of the push-button extends through the rotary switch step-magnet, and the back contacts of a relay to battery. That circuit actuates the step-magnet armature which causes the stepping pawl to engage the next tooth of the ratchet wheel and also causes a pair of contacts associated with the armature to close. The closure of the latter contacts completes a circuit for the operation of the relay which opens the circuit through the step-magnet and causes the armature to release. The release of the armature advances the wipers one step and reopens the armature contacts which release the relay. The release of the relay re-establishes the circuit condition which existed when the push-button was first depressed. Another operation will occur as just described and those operations will repeat until the marked position of the rotary switch is reached by the wipers. When the position is reached a circuit will be completed through a second pair of contacts of the push-button, a stator contact and one of the wiper contacts of the rotary switch, a second winding of the relay to battery. That circuit holds the relay operated and thereby prevents re-establishing the operate circuit through the rotary switch step-magnet. Thus, the rotary switch wipers are caused to be advanced over the switch positions and stopped when the marked position is reached.

Direct and Sharing Switching

Economies were obtained in the push-button switching equipment used in the Philadelphia and Cincinnati offices by using a combination of "direct" and "sharing" switching arrangements. Each intraoffice transmitter is provided with four rotary switches individual to that transmitter, by means of which it can be switched directly to 72 heavily loaded destinations, and can be switched to rotary switches, common to 11 or 13 transmitters, for reaching 198 destinations. The intraoffice circuits for heavily loaded sending destinations are terminated on the stator positions of the rotary switches which are individual to the transmitters while the intraoffice circuits of the lightly loaded sending destinations are terminated on the stator positions of the sharing rotary switches. Figure 12 shows diagrammatically the direct and sharing rotary switch arrangement for a group of 13 transmitters.

Figure 11. Two types of rotary switches

The transmitter is connected to the rotor of the direct selector switch. The intraoffice circuits of 22 destinations are connected to the first 22 positions of this switch. The twenty-third position is connected to the sharing selector switch, the twenty-fourth position to the *A* direct connector switch and the twenty-fifth position to the *B* direct connector switch. Thus; through the direct selector switch and the direct connector switches *A* and *B*, the intraoffice transmitter can be switched to any one of 72 destinations through equipment which is individual to the transmitter. With these direct switching facilities, all 13 transmitters can be switched to the same destination or to 13 different destinations out of the 72. Sharing connector switches 1 to 24 are provided for the remaining 198 destinations, which gives a total of 270 destinations, the capacity of the push-button switching turrets.

An intraoffice transmitter is connected to one of the destinations terminated on the sharing switches by its associated direct selector switch advancing to the twenty-third position, by its associated sharing selector switch advancing to the proper position to make connection with one of the sharing connector switches which serves that destination, and by that sharing connector switch advancing to the position to which the intraoffice circuit of that destination is connected. All of these switches self-step simultaneously and their action is controlled by a destination push-button, depressed in the push-button switching turret.

From the foregoing description it will be seen that in the push-button reperforator-switching system, telegrams are received on printer-perforators which record them on a paper tape in the form of printed characters and perforated holes corresponding to the printing telegraph code. These printed-perforated tapes are passed through intraoffice transmitters that transmit the messages across the office where they are received on intraoffice reperforators which again record them on a paper tape in the form of perforated holes corresponding to the printing telegraph code (but not printed) and this latter tape is passed through a line transmitter which transmits the signals over an outgoing circuit to a distant office. The intraoffice transmitter conductors are connected to the conductors of any desired intraoffice circuit through the contacts of rotary switches which in turn are controlled by push-buttons in switching turrets. Intraoffice transmitters, intraoffice reperforators, and automatic numbering machines function under control of impulse units. The transmitter allotter functions to allow but one intraoffice transmitter to be connected to a given intraoffice circuit at a time, and automatically establishes a new connection to an intraoffice circuit as quickly as preceding connections have been released; and each intraoffice connection is automatically released just as soon as the intraoffice transmitter sends the last character of the telegram for which the connection was established. These are the fundamentals of push-button reperforator-switching.

There are many supervisory controls used in this system that are beyond the scope of this paper to be described in detail. Various signal lamps and buzzers function to warn switching clerks, supervisors, and regulating attendants of unusual conditions. A broadcast system of microphones and loud-speakers is provided in order that switching aisles, transmitting aisles, supervisors, and regulating attendants may have instantaneous communication with one another as needed. Special book switching positions are used for assorting and retransmitting multiple-address telegrams where a single copy of the text is to be transmitted to a large number of addressees. There is a master key transmitting position from which periodic market quotation messages are transmitted simultaneously into as many outgoing circuits as desired. Special switching positions are provided for switching to "tie-line" patrons in the same city.

Western Union's mechanization program calls for 15 major offices to be

Figure 12. Direct and sharing rotary switch arrangement

converted to reperforator-switching, by 1950. Of these 15 offices, 11 will include push-button type of operation just described. At that time, these 15 offices will serve as distribution centers for the entire country. Other large terminal offices will have a somewhat different type of reperforator-switching.

Pole Fires Due to Insulator Contamination

W. H. WICKHAM

M. S. OLDACRE
FELLOW AIEE

Synopsis: Wood poles and crossarms of overhead electric lines may become ignited and damaged when the surface of the insulators and wooden parts become contaminated by industrial dust and upon the occurrence of certain atmospheric conditions. A study was made in the laboratory of all the factors which might contribute to the causes of pole fires. Conditions of dirt and fog and also burning of poles similar to occurrences in the field were reproduced. An explanation of the causes of pole fires was found and finally a simple and effective method of preventing the burning was developed.

WHILE pole fires are not unusual on overhead electric lines, there usually is little opportunity to investigate the causes or propose remedies. A few cases of pole fires have occurred in the Chicago area and under circumstances that gave a basis for further laboratory study that might be of value in reducing such troubles in the future.

The circumstances surrounding these fires were peculiar in that on similar lines, under apparently the same conditions, no burning occurred. This prompted an investigation of the various factors contributing to pole burning in an attempt to evaluate the importance of the different variables and to develop means of prevention.

Analysis of Variables

Contamination

The lines involved in this study were in an industrial district where contamination with dirt from adjacent industrial plants was very heavy. The fires occurred during periods of heavy fog or light drizzle following prolonged periods of dry weather which permitted the accumulation of contaminants on the line structures. This agrees with other investigators' findings that pole fires are caused by contamination and fog.

In the case investigated there were wooden poles on both sides of a street carrying 33,000-volt lines. While there was no reason to believe that contamination was different on the two sides of the street, the observation was made that burning occurred only the east side of the street and none on the west side of the street. It was obvious, therefore, that a number of additional variables must be contributing factors in the production of pole fires.

Design of Line

At the present time the poles on both sides of the street each carry two 33,000-volt lines. The structures are wooden poles with three wooden crossarms, one line on each side of the pole. The two lines on each pole have the same phase designation for the conductors on the middle arm and different phase designations for the conductors on the top arm and on the bottom arm, that is, on a specific pole the phase arrangement from top to bottom might be *A B C* for one line, and *C B A* for the other line. The observations showed that the lines on the east side of the street were noisy due to electrical discharges during periods of fog or drizzle while the west side lines were quiet. Furthermore, careful inspection revealed that the lines on the east side of the street showed numerous cases of tracking on the arms, while little or none was observed on the lines on the west side of the street.

At the time the pole fires occurred, the poles involved carried two lines while the poles on the other side of the street carried only one line. From theoretical considerations, the double-circuit poles are more susceptible to pole fires than the single-circuit poles under the existing phase arrangements, because the leakage current density is greater for double-circuit poles than for single-circuit poles, especially in the middle gain, that is, the contact surface between the middle arm and the pole. That pole fires tend to start at this point agrees with field observations. Further investigations, however, indicated that this was not the complete explanation for the difference in behavior of the lines. Shortly after these pole fires occurred an additional line was installed on the west side of the street, so that from then on there were double-circuit poles on both sides of the street. While there were no subsequent pole fires on either side of the street, it was observed that the lines on the west side of the street remained quiet and free of tracking while discharges were observed on the east lines.

Since the constructions are so similar, it became apparent that additional variables must have been responsible for the difference in the behavior of the lines.

Insulators and Pins

The next set of variables studied were the insulators and pins. Practically all the insulators on the east lines were of one design, while the insulators on the west lines were of different designs including the design used on the east lines. Furthermore, all pins on the east lines were truss pins while the standard round pins were used on the west lines. Because the insulators and pins on the east lines were predominantly of one type, the first laboratory studies were made on the characteristics of insulators and pins alone. The results of the laboratory tests, to be described later, indicated that the differences in design of insulators were not sufficient to account for the different performances of the lines.

Paper 48-319, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Wood Structures

As a next step in the study of variables affecting pole fires, attention was concentrated on the treatment of the wood structure. A survey revealed that all poles were creosoted on the east lines while only three per cent of the poles were creosoted on the west lines. Furthermore, all arms were creosoted on the east lines while only two-thirds of the arms were treated on the west lines. The laboratory studies, therefore, proceeded to include the wood members with various combinations of treatment. The results showed that the treatment is an important factor in producing pole fires.

Laboratory Studies

Insulators and Pins

In the study of insulators under conditions of contamination and fog, a procedure was used in the laboratory similar to the one described in another paper.[1] The insulators were dirtied with a mixture of fly ash and Portland cement by a method of alternate fogging and dusting while energized at 19 kv which is the line-to-ground voltage in service. The amount of dust and the directions of the nozzles were so adjusted as to give a pattern and degree of contamination similar to that observed in the field. Except for the direction of the nozzles, the arrangement for contamination and fogging was similar to the one shown in Figure 1 of the paper just mentioned. The nozzles were modified so that the top nozzle formed an angle of 45 degrees with the vertical and the lower one an angle of 30 degrees. The top nozzle was directed upwards against the rim of the top shed and the lower one into the recess around the pin.

This method gave closely reproducible results as determined from electrical characteristics. The amount of the contamination was adjusted so that the fog-wet flashover was approximately 28 kv or $1^1/_2$ times the phase-to-ground voltage in service. This degree of contamination was established previously from service experience as a serious condition. Table I compares test results for artificially-contaminated insulators with field-dirtied insulators which had been installed on the same poles that carried the 33-kv lines or on adjacent poles. Some of these insulators were energized while mounted on the poles in the field and some were not energized. It can be seen from Table I that the effect of field contamination upon flashover and surface resistance was reasonably similar to the effect of laboratory contamination.

The eight different insulators in operation on the four lines are shown in Figure 1. The effect of dirt and fog on the flashover of these insulators is shown in Figure 2. Insulator 6, which is the one used predominantly on the east lines shows the lowest value under fog and dirt conditions. However, there were other insulators that were not much better. The data show that the type of pin had little effect.

Since pole fires are essentially a leakage problem rather than a flashover phenomenon, studies were made of the surface resistance under fog and dirt conditions. The results are shown in Figure 3. Insulator 6 was the poorest in these tests. However, where the contamination has reached a degree so that sufficient current flows to start a pole fire, the surface resistance of the insulator is so low that it is only a small part of the leakage resistance of the insulator-wood circuit. While the lowering of the resistance of insulators due to contamination is an important factor in creating pole fires, the differences between the resistances of the contaminated insulators of the eight different types tested appear of little significance. The marked difference between insulator 1 and the others is due to the absence of a metal thimble in this insulator.

Under fog-dirt conditions the flow of leakage current is not uniform. Milliammeter charts showed current pulses varying over wide limits. These variations were caused by drying of portions of the insulators under the effect of current flow and subsequent arcing over

Figure 1. Types of 33-kv insulators covered by investigations

Figure 3. Surface resistances of 33-kv pin-type insulators (contaminated, fog-wet)

these dried portions. These current-time charts did not show any consistent differences between the various insulators. Similarly, measurements of the total energy flow by means of a sensitive watt-hour meter indicated no significant differences between the insulators.

Pole Fire Tests

In order to study the various factors contributing to pole fires, a laboratory setup was made reproducing, as closely as practical, the actual service conditions. Pole fires were produced under conditions of dirt and fog, resulting in burning similar to that which has been observed in the field.

The laboratory setup consisted of a section of pole, a crossarm, and an insulator. A gain was cut in the section of pole and the crossarm bolted to it. A second bolt through the pole removed some distance from the gain was the ground electrode. The length of crossarm in the circuit varied from $1^1/_2$ to 5 feet and of the pole from 1 to 3 feet in the series of tests. The insulator, contaminated with fly ash and cement mixture, was mounted on a metal pin on the crossarm. Wet water vapor, supplied by low pressure steam, was directed at the pole assembly to simulate fog conditions. This was sometimes supplemented by a fine water spray from an atomizer.

The procedure in producing a pole fire was as follows. The test voltage of 19,000 volts was applied between the top of the insulator and the grounded bolt in the pole. This voltage is the line-to-ground voltage on the 33,000-volt transmission lines in service. Fog was directed to strike the insulator first, then envelop the crossarm, and finally cover the pole between through bolt and grounded bolt. Current was measured by a recording milliammeter connected in the ground lead.

The observations and measurements made in a large number of such tests, not all of which resulted in pole fires, show the importance of the various factors which in combination produce pole burning.

The serious type of fire is the "pocket fire." The burning is most often a smoldering without open flames but the result is a deep "pocket" burned in the pole, and some burning of the crossarm. Burning may occur also on the opposite side of the pole at the through bolt, but only one such case was observed in all the tests.

The magnitude of current necessary to produce a pole fire cannot be specified. In some tests fires occurred with currents as low as 5 milliamperes. In other tests currents considerably in excess of 5 milliamperes did not initiate fires. It is not the magnitude of current but the concentration, or current density at some point usually in the region of the gain, which gives rise to the serious burning.

The immediate cause of burning is an arc in a highly stressed area. The arc must exist at a point where fuel is present in the form of wood sufficiently dry to burn or from the wood impregnant. Such a highly stressed area is found in the region of the gain. Where pole and crossarm meet the wood is relatively dry and furthermore, the current must take a cross grain path in passing from crossarm to pole. The potential distribution curve of Figure 4, plotted from data taken on a test setup which had been subjected to fog, shows that nearly one-half of the voltage drop exists in the short section of the circuit represented by the gain. The relatively dry wood in this area supplies fuel also. The chimney effect created between the pole and crossarm and the mutual heating of pole and crossarm help to sustain the burning. Most of the fires which occurred in the laboratory tests were found to originate at the gain. Field observations are in agreement with the laboratory results. It should also be noted that most, or all of the conditions, set forth as causes for burning may also occur in cracks in the wood and around the hardware. One fire was started on the back of the pole at the through bolt. Cracks were observed to aid the spread of burning.

Not all the tests resulted in pole fires. By means of surface resistance measurements, it was found that current was greatly reduced and burning prevented by drying of the insulator due to heavy leakage current or by creation of sufficiently long areas on the crossarms or poles.

On the insulator, the drying occurred usually in the area around the pin or the cap where the leakage current density was highest. On the crossarm, drying took place in areas of high resistance. Such areas frequently showed arcing which resulted in light burning or "tracking" on the surface of the wood. On short specimens of crossarm this tracking sometimes progressed the length of the arm and resulted in serious burning. On longer specimens, which more nearly represent the field conditions, tracking resulted most often in drying with a reduction in leakage current before serious burning occurred. The pole portion of the wood circuit acts in much the same way.

The treatment, or impregnation, of the wood of pole and crossarm is an important factor in the occurrence of fires. Untreated pole wood was found to absorb surface moisture readily and a plentiful supply of moisture was necessary to produce the low resistance and the leakage current necessary for burning. On wood freshly impregnated with creosote the moisture collected on the surface in more or less isolated droplets, thus limiting the leakage current. However, after exposure to weather the creosote was leached from the outer surface, yet moisture could not penetrate far into the wood. The result on such specimens of wood was a low-surface resistance and high-leakage current in fog. The creosote impregnant also furnished fuel for burning. The occurrence of fires was found to be much more frequent in creosote-impregnated wood than in untreated wood in the laboratory tests. This is in agreement with field observations that under fog conditions the east lines carried on creosoted poles were noisy and subject to tracking.

Figure 4. Potential distribution on contaminated fog-wet insulator, arm and pole

Preventive Measures

From a consideration of the factors governing the occurrence of pole fires, it was concluded that an effective method of preventing or minimizing the danger of pole fires would be one which eliminated the arcs in the highly stressed region at the gain, without reducing too greatly the resistance of the gain since it is a large part of the total resistance of the wood circuit.

The method which proved satisfactory was calking the gain lines, that is, the junction lines between pole and crossarm, with a plastic compound. Laboratory studies indicated that the calking compound should have the following characteristics:

1. The compound should be soft and adhesive.
2. It should retain its plastic and adhesive properties under prolonged weathering.
3. It should be of a type which can be applied with a gun as a fillet into the gain lines.
4. It should be slightly conductive but not

enough to materially alter the resistance of the gain of the wood circuit.

By laying a fillet of the plastic compound into the gain lines the arcs in the danger zone around the gain are eliminated. The total resistance of the wood circuit is not materially reduced and therefore the leakage current is not increased. In the laboratory tests the method proved very effective. No fire originated at the gain in any setup where the calking compound was applied. It does not, of course, eliminate the possibility of fires at the hardware or at cracks in the pole, but such fires are in the minority. Application of the compound to existing lines, with calking gun, is simple.

Other suggested methods for eliminating fires at the gain were tried also, but were found by test to be less satisfactory. One method was the installation of a conducting layer in the form of a metal liner in the gain between pole and crossarm. Unless the fit is very good and the metal in close contact with the wood, arcing occurs between wood and metal, much the same as between pole and crossarm in the ordinary gain, and protection is not achieved.

A second method of protection tried was bonding, that is, the wrapping of both pole and crossarm with wire on all sides of the gain and connecting all bond wires together. This method reduces the resistance of the wood circuit by eliminating the resistance of the gain and increases the voltage stress across pole and crossarm, thus increasing the leakage current and the tracking on the surface of the wood members. Furthermore, the bond wires may in time become loose, giving rise to arcing and making a fire possible at the points of application of the bond wire in the same way as at the hardware.

Because of simplicity in application and effectiveness in preventing burning, it was concluded that calking of the gain is the best of the methods tried and will prevent most pole burning.

Conclusions

1. Pole fires cannot be attributed to any single factor but are the result of a combination of conditions to be fulfilled simultaneously.

2. Insulator contamination is a requisite for pole burning. However, eight common types of insulators studied on two types of pins in this investigation did not show sufficient differences under conditions of contamination and fog to conclude that pole burning is much more likely with one than with another.

3. Burning is more apt to occur on creosote-impregnated wood than on untreated wood.

4. Pole fires are most likely to occur at the gain.

5. An effective method of preventing most pole fires is calking around the gain with a suitable compound.

A-C Resistance of Large Size Conductors in Steel Pipe or Conduit

R. J. WISEMAN
FELLOW AIEE

Synopsis: The determination of the proper conductor size to carry a given power load on cables installed in steel conduits or pipes has been subject to assumptions which were not too satisfactory. The Insulated Power Cable Engineers Association engaged the Electrical Testing Laboratories to conduct a research project to determine the effective a-c resistance of large conductors installed in steel pipes. This paper reports the results of the research and gives suggested values of ratio of a-c to d-c resistance for conductor sizes up to 2,500,000 circular mils. It is felt that more accurate and uniform calculations of current carrying capacity of cables in conduit in air, or in pipe in the ground can be attained by use of the a-c/d-c conductor resistance ratios set forth herein, than by assumptions used previously, and therefore the data reported herein will be of benefit to both the manufacturer and the power user.

THE CURRENT carrying capacity of power cables installed in conduits or steel pipes is a function of the a-c resistance of the conductors, as well as the thermal resistance of the insulation and the allowable operating temperature. It is possible to compute the thermal resistance, and experience has set up the allowable operating temperature. Our knowledge of the a-c resistance up to the present has been very meager and not too reliable. In 1935, there was a paper presented before the AIEE, entitled Resistance and Reactance of 3-Conductor Cables,[1] which gave values of a-c resistance for 3-conductor cables in lead sheaths. The conductor sizes, however, were not over 1,000,000 circular mils, whereas much larger sizes are used in conduits. It was not certain that it would be possible to take the values reported in this paper and use them for conduits, as the steel binder used was thin, open spiralled, and paralleled the lead sheath, whereas in the case of a conduit we have a comparatively heavy wall and usually no paralleling grounding shield over the insulation.

Realizing the importance of knowing what this a-c resistance should be, the Insulated Power Cable Engineers Association sponsored a research to make tests on large size conductors when installed in conduits and to determine the increase in resistance over the d-c resistance when alternating currents were carried.

As this study was considered of major interest to all who use cables in pipes or conduits and particularly to cable manufacturers who are required to determine the proper cable size for a given power load to be carried, the Insulated Power Cable Engineers Association approached the cable manufacturers* who contributed to a fund for the investigation. In addition, the association itself appropriated an equal amount.

The research committee of the Association was delegated to supervise the research and was given permission to have the Electrical Testing Laboratories carry out the tests. A program was set up to guide Electrical Testing Laboratories in its work. A summary of the program is as follows.

Object of Research

The purpose of this investigation is to determine the a-c/d-c resistance ratio of large conductor cables when installed in steel pipe. To cover a wide range in conductor size, the cables to be tested will be: 750,000, 1,500,000, and 2,500,000 circular mils with standard concentric stranding; and 2,500,000 circular mils with segmental construction; all to have a 1/8-inch dry paper nsulation with a braid or tape covering. It was appreciated that there would be a lower ratio for cables with oiled strands, and therefore tests should be made to determine the ratio for such a condition, but funds being limited, it was decided to confine tests to dry strands. The length of conduit in each case is to be 20 feet.

In the setup for the tests of each cable, provision is to be made for circulating single-phase 60-cycle current; balanced 3-phase 60-cycle current; and direct current. The measurements to be made are to include d-c resistance, a-c resistance and reactance under the various conditions indicated in the following and to be made in each case over a range of currents up to well above the normal rating for the conductor size.

Tests on Data

The schedule of tests, each at not less than five values of current, is as follows:

1. All sizes, single conductor in air, with 48-inch loop, single-phase current.
2. All sizes, three bound together in triangular arrangement in air, 3-phase current.
3. Same as (2) with the 750,000-circular-mil conductors, in a 4-inch conduit; the 1,500,000-circular-mil conductors in a 5-inch conduit; and both types of 2,500,000-

Paper 48-254, recommended by the AIEE insulated conductor committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted May 25, 1948; made available for printing August 17, 1948.

R. J. Wiseman is chairman of the Insulated Power Cable Engineers Association research committee and is associated with The Okonite Company, Passaic, N. J.

Personnel of the IPCEA committee on research: R. J. Wiseman, chairman, R. W. Atkinson, W. A. Del Mar and G. B. Shanklin.

* The wire and cable manufacturers who contributed to the funds for this research are: American Steel and Wire Company, General Electric Company, Habirshaw Cable and Wire Division (Phelps Dodge Copper Products Corporation), Kennecott Wire and Cable Company, The Kerite Company, National Electric Products Corporation, The Okonite Company, The Paranite Wire and Cable Corporation, Rockbestos Products Corporation, John A. Roebling's Sons Company, and the Simplex Wire and Cable Company.

The IPCEA committee wishes to express its appreciation to members of their companies' staffs for the help given in preparing the program and analysing the tests, particularly F. H. Buller, M. H. McGrath, L. Meyerhoff, J. H. Palmer, and R. C. Waldron.

11. Same as (10) but cradled to shape as if lying in a 6-inch conduit.

12. Same as (10) but in a 4-inch conduit.

13. The three 2,500,000 circular-mil concentric cables in air but cradled to shape as if lying in a 6-inch conduit, 3-phase current.

14. Same as (13) but in a 6-inch conduit.

Notes—In all tests in pipe, the 3-conductor cable formed by the triangular arrangement is to lie on the bottom of the pipe, as in actual installation.

Due to the size of the conductors and the short lengths for test, it was not possible to twist the conductors to form the usual arrangement of a 3-conductor cable.

During the period of testing, conferences were held to discuss results, and it became necessary to either modify tests or add new tests in order to obtain the desired results. Although we were interested in 3-phase testing of the cables in a conduit, to properly appreciate what is taking place, it was necessary to make single-phase and 3-phase tests on the cables in air prior to installing in the conduit. Many interesting problems arose, such as location of potential leads, time for holding the current at each value before taking final readings of conductor temperature, and external magnetic field effects arose which had to be solved.

This paper gives the results of the tests for a-c resistance obtained by Electrical Testing Laboratories, a discussion of them, and what conclusions can be made.

The method of testing, as well as a discussion of some of the problems which arose, will be found in a companion paper entitled Problems in the Measurement of A-C Resistance and Reactance of Large Conductors by E. H. Salter[2] of Electrical Testing Laboratories, who carried out the tests and prepared the official report for the Insulated Power Cable Engineers Association.

At the same time that the a-c resistance was being determined, it was possible to also measure the reactance. Wm. A. Del Mar, a member of the research committee, has a companion paper entitled Reactance of Large Cables in Steel Pipe or Conduit[3] in which he reports on this part of the research.

Currents were applied to give a curve of resistance versus conductor temperature up to about 80 degrees centigrade so that the effect of temperature on the a-c/d-c resistance ratio could be noted.

Results (In Air)

The general case is somewhat limited in its application and precision by the relatively meager extent of the data which could be secured within the bounds set by

* Cradled as in 6-in. electric conduit.

the funds available. However, the accuracy of the application is such that it is practical to obtain rather simply a useful solution for most conditions within the general scope of the project. Reasonable accuracy of estimate now can replace what were often merely controversial guesses. The data secured will greatly improve the accuracy of loss calculations and of current ratings. This should improve utilization of materials and, at the same time, help guard against dangerously high operating temperatures with resultant reduction of useful life.

Table I gives the data obtained for the 750,000-circular-mil conductor, and Table II for the 1,500,000-circular-mil and 2,500,000-circular-mil conductors.

Figure 1 shows the change in d-c and a-c resistance and ratio with temperature for the 1,500,000-circular-mil conductor in a 5-inch conduit. These curves are typical in form for all conductor sizes tested.

The measurements of a-c resistance for single-phase setup in air when compared to calculated values gave very close agreement which indicates that the test method used gives true values. For example: Table III compares the value of a-c and d-c resistance difference and ratio for the 1,500,000-circular-mil concentric stranded conductor as found by test and computed by means of the formula:

$$x = 0.02768 \sqrt{\frac{f}{R}}$$

where f is the frequency, R is the d-c resistance in ohms per 1,000 feet at the conductor temperature, and after calculating x, the skin effect factor may be found from tables such as that on page 3–23 of the Electrical Engineers Handbook by Pender and Del Mar.[4]

The foregoing formula for x can be converted over to one in terms of the conductor area and a temperature correction factor for resistance. If A is the area in circular inches and $b = 1 + 0.00393\ (t - 20)$ is the temperature correction factor referred to 20 degrees centigrade, then for $f = 60$ cycles,

$$x = 2.08\sqrt{A/b}$$

The same agreement has been found for other conductor sizes of concentric stranding.

Incidentally, the single-phase test on the 2,500,000-circular-mil segmental conductor gave a good chance to check the method for calculating the skin effect factor ratio of this design, namely, it shall be considered to be the same as that for a conductor having 44 per cent of the total area.

Table IV compares the skin effect factor for all sizes tested at 20 degrees centigrade. The actual ratios by test compare very well with calculated ratios. A study of the change in a-c resistance when making the 3-phase tests in air indicated an almost constant difference between the a-c and d-c resistance for a given conductor temperature. It was suggested by Louis Meyerhoff of the General Cable Corporation that it is possible to compute the a-c resistance for any temperature provided that the value for one temperature is known and if the a-c/d-c ratio is taken for that temperature, working backwards, determine an effective x, then correct this value of x for each temperature and find the new skin effect factor. Table V shows this comparison for the 1,500,000-circular-mil conductor spaced 1.70 inches in air. The values at 20 degrees centigrade were taken as reference points. The agreement at other temperatures may be considered as good and sufficiently accurate to use.

Results (In Pipe)

The same reasoning can apply for the cables in a pipe as shown in Table VI for the same 1,500,000-circular-mil conductor. The difference between a-c and d-c resistances, computed and by test, is not great. The ratio comparison is fairly good and can be taken practically. Figure 1 shows the a-c and d-c resistance and the ratio of these resistances as a function of temperature.

The Meyerhoff method gives a workable means for determining the a-c re-

sistance, but it requires making measurements at one temperature for each conductor size, spacing, and size of pipe. As this is not practical, it is necessary to find a method which will give a curve showing the a-c/d-c ratio for each conductor size.

Where large conductors are close together in air, as when spaced by the insulation and coverings thereover, there is an increase in resistance over the d-c resistance due to:

1. The skin effect within the conductor.

2. The proximity effect which is the loss produced in one conductor by the current flowing in the adjacent conductor or conductors.

It is to be recognized that this distinction between the two sources of loss (1) and (2) is not precise, inasmuch as there is mutual interaction that prevents a precise application here of the principle of superposition. The separation is, however, very convenient and helpful in the case of the usual cable conductor. Where cables are placed inside a metallic pipe, there is an additional increase in a-c resistance over that when the cables are in air, this being due to the influence of the pipe upon the magnetic field produced in the conductors.

In the case of a ferrous pipe, there is caused a distortion and strengthening of the magnetic field which changes the proximity effect between the conductors. In this case, there are three sources of loss.

(1) Skin effect.

(2) Proximity effect due not merely to the current in the adjacent conductors but to the field distortion caused by the pipe.

(3) Loss in the pipe itself caused by hysteresis and eddy currents produced by the magnetic field.

Table VI shows also that the difference between the a-c and d-c resistance is nearly independent of temperature. Thus, for cables in pipe, as for cables in air, this simple fact may be used for obtaining the a-c resistance at different temperatures, or the somewhat more accurate Meyerhoff method may be used.

In order to determine how much of the added loss which is occasioned by the presence of the pipe is in the pipe and how much is due to added loss in the conductor, a special series of tests were made by calorimetric methods. The rate of rise of temperature of the pipe was determined for a given test condition and that was evaluated in terms of watts by determining the rate of rise of pipe temperature with known loss. These tests were made on the 2,500,000-circular-mil concentric stranded conductors. With these it was found that approximately 10 per cent of the total losses existed in the pipe. This is equivalent to 16 per cent of the extra (difference between a-c and d-c) losses. It is recognized that the particular division of losses is applicable only to this particular size and combination. However, it may be expected that using this percentage will give better temperature rise calculations than would the assumption that all losses are concentrated at the conductor.

Table VI. Comparison of A-C and D-C Resistance with Temperature as Computed and by Test for 3-Phase Setup

1,500,000 Circular Mils in 5-Inch Pipe—1.70-Inch Spacing

Temperature, Degrees Centigrade	Computed (Meyerhoff) Resistance, Ohms Per Thousand Feet A-C	D-C	Difference	Ratio	By Test Resistance, Ohms Per Thousand Feet A-C	D-C	Difference	Ratio
20	0.0131	0.0069	0.0062	1.90	0.0131	0.0069	0.0062	1.90
40	0.0138	0.0075	0.0063	1.84	0.0135	0.0075	0.0060	1.80
60	0.0142	0.0080	0.0062	1.78	0.0140	0.0080	0.0060	1.75
80	0.0148	0.0085	0.0063	1.74	0.0145	0.0086	0.0059	1.69

As a specific procedure, and in view of the recognition that the applicability of this test is limited without data on other sides, it has been proposed that, as a workable basis, 20 per cent of the extra losses be assumed to be in the pipe and the remaining 80 per cent in the conductor when the currents in the three conductors are balanced. This should be considered an acceptable basis within the limits of presently available information.

It has also been proposed that a single curve be used for the ratio Rac/Rdc as a simple function of the conductor size. This makes it independent of insulation thickness. It is also independent of pipe size on the assumption that each construction will be housed in the appropriate pipe. This suggestion has much to commend for its great simplicity and because it actually fits the test data so well. Detailed comparisons are shown later herein.

In order to find a closer correlation for specific insulation thicknesses and pipe sizes, R. W. Atkinson of the General Electric Company has proposed the use of certain empirical formulas. For the skin effect, the well-known method referred to previously could be used. The proximity effect would be determined as for the conductors in air; (See the Appendix for the Arnold method of computation); for the proximity effect in the pipe this value of proximity in air would be multiplied by F,

where

$$F=\frac{4.2\,S^2}{pd^2},$$

where S is the spacing of the conductors (center to center), p is the inside diameter of the pipe, and d the diameter of the conductor. The sum of the skin effect and proximity effect so determined would be considered as the added (a-c as compared with d-c) resistance within the conductors themselves. The increase in effective resistance due to loss within the pipe itself would be taken as

$$PL=\frac{0.00150S^2}{p}$$

ohms per thousand feet.

These formulas were worked out to express somewhat rationally the effect of the various parameters but essentially no claim is made for them, except that they may give a somewhat broader application to the data than can be done where the conductor separation and pipe size are not taken into direct account.

Table VII gives a comparison of com-

2,000	1.84	1.86
2,500	2.10	2.09

puted values on the foregoing basis for the conductor sizes, spacings, and pipe sizes used by Electrical Testing Laboratories and the ETL values.

The agreement between computed and test values is probably as good as could be expected in view of the fact that there is no mathematical analysis available to determine the increase in resistance except to some degree for the cables in air and empirical formulas have been set up for the effect of magnetic pipe.

In view of the fair agreement between the Electrical Testing Laboratories and computed values of R_{ac}/R_{dc} as indicated in Table VII, calculations at 70 degrees centigrade were made for a large number of conductor sizes and insulation thicknesses from 1/8 inch to 1 inch. A pipe diameter was taken such that the area of the insulated conductors was equal to 40 per cent of the area of the pipe. It was necessary to take the exact pipe diameter in order to be able to get a curve. If this were not done, the ratios spread out badly. In actual practice, the nearest standard pipe would be used, accepting whatever error in the ratio which would exist. This error is small as it affects the proximity and pipe loss terms which are two terms of a total of four terms, one of which is the d-c resistance which is much the largest of all. The ratio R_{ac}/R_{dc} did not vary greatly. For a 250,000-circular-mil conductor from 1.04 to 1.05; a 750,000-circular-mil 1.24 to 1.27; a 1,250,000-circular-mil 1.54 to 1.61; a 2,000,000-circular-mil 2.10 to 2.14. If the five values obtained (for t = 1/8 inch, 1/4 inch, 1/2 inch, 3/4 inch and 1.0 inch) were averaged, the variations therefrom are not great.

Table VIII gives the average ratio of R_{ac}/R_{dc} for total losses at 70 degrees centrigrade and are taken from a curve plotted with the Electrical Testing Laboratories test values. In comparison, the last column gives the computed average values as obtained by means of the empirical formulas. It is in order to use the column giving the Electrical Testing Laboratories values, but if one wishes, he could use the computed values within the accuracy of the test results.

Table IX gives a comparison of the ratio of R_{ac}/R_{dc} at the conductor based on the suggestion of G. B. Shanklin of the General Electric Company that 80 per cent of the extra losses be assumed to exist in the conductor and based on the empirical formula. The agreement between the proposed values and the computed average values is very good. Either could be used but to be consistent, if the Electrical Testing Laboratories values for the ratio of R_{ac}/R_{dc} for total losses as given in Table VIII are used, then the proposed ratios for the losses at the conductor should be used.

Up to the present, concentric-stranded conductors have been discussed. Tests were also made with a 2,500,000-circular-mil segmental conductor cable.

A definite decrease in the ratio R_{ac}/R_{dc} was noted as compared to a concentric-stranded conductor of same area as shown in Table VII. When the construction of the segmental conductor is considered, this is not surprising. It is known that the skin effect is much less. Due to the spirality of the segments, it is fair to state that the proximity effect is less. Therefore, the skin effect plus proximity effect in air should be less. This is shown to be true by the tests in air of both conductor constructions, namely for 20 degrees centigrade, R_{ac}/R_{dc} = 1.93 for concentric stranding and 1.49 for segmental construction. (See Table II.) When the cables are in a pipe, it is not certain that there will be the same amount of pipe loss. It cannot be greater than for a concentric-stranded conductor, but it can be less. If it is assumed to be the same, then it is possible to use the same formula for computing the increase in resistance due to pipe loss (PL = 0.00150 S^2/p ohms per thousand feet) and then correct the factor by which the proximity of a concentric-stranded conductor is multiplied to get the assumed proximity loss due to the pipe. This was done and it was found that if the constant 4.2 in the formula were changed to 2.4, that is,

$$F = \frac{2.4S^2}{pd^2}$$

a value of proximity was obtained which gave a reasonable close value of total loss to that found by Electrical Testing Laboratories: namely at 70 degrees centigrade R_{ac}/R_{dc} = 1.74 by computation and 1.76 by Electrical Testing Laboratories. It is admitted that considerable liberty has been taken with assumptions. It would have been much better, if it were possible, to have tests made on other sizes of segmental conductors. In view of very limited data (only one conductor size studied), it is felt that at the present time we postpone setting up a tabulation of R_{ac}/R_{dc} for segmental conductors as for concentric conductors, as given in Tables VIII and IX. Some manufacturers are now making tests with several conductor sizes and will give the results to the Association when completed.

As originally planned, all tests were made with the three conductors tied together in triangular arrangement. Question arose as to what the effect of the cables lying in a flat arrangement would have on the a-c resistance. Tests were made on the 750,000-circular-mil conductor and the 2,500,000-circular-mil concentric-stranded conductor. These are reported in the Electrical Testing Laboratories report and given in Tables I and II.

Table X gives a comparison of the ratio R_{ac}/R_{dc} for the 750,000-circular-mil conductor for triangular and flat arrangements in air and in pipe. The cables with flat arrangement in air were cradled to give the shape that they would take when lying in a 4-inch conduit.

Table X. Comparison of R_{ac}/R_{dc} for 750,000-Circular-Mil Conductor When Arranged in Triangle and Flat

	Temperature, Degrees Centigrade 20	40	60	80
Triangle air	1.157	1.137	1.120	1.103
Flat air	1.067	1.077	1.087	1.097
Triangle pipe (4 inch)	1.304	1.288	1.274	1.258
Flat pipe (4 inch)	1.256	1.237	1.219	1.202

Placing the conductors in a flat arrangement reduces the ratio R_{ac}/R_{dc} about 5 per cent. This is surprising, as the magnetic field is more unbalanced and a greater amount of flux will exist in the pipe; therefore, we would expect a higher loss. It would appear that the proximity effect is decreased. This is indicated in the re-

Table XI. Comparison of R_{ac}/R_{dc} for 2,500,000-Circular-Mil Concentric Stranded Conductor Arranged in Triangle and Flat

	Temperature, Degrees Centigrade 20	40	60	80
Triangle air	1.934	1.897	1.844	1.780
Flat air	2.026	1.994	1.963	1.933
Triangle pipe, 6 inch	2.637	2.524	2.418	2.327
Flat pipe, 6 inch	2.982	2.853	2.724	2.595

sults for the tests in air where a lower ratio was also found.

Table XI gives a comparison of the ratio R_{ac}/R_{dc} for the 2,500,000-circular-mil concentric-stranded conductor in triangular and flat arrangement, and in air and in a 6-inch pipe.

In this case, there is an increase in the ratio for both in air and in pipe, about 5 and 13 per cent respectively. This is directly opposite to the results obtained for the 750,000-circular-mil conductor. It is difficult to understand why such diametrically opposite results were obtained. It would seem as if the results for the 2,500,000-circular-mil conductor were more logical, yet should the results for the 750,000-circular-mil conductor be ignored? It would be more conservative to assume that there is an increase in the ratio and if a 15 per cent increase is taken, for a flat or random arrangement, as compared to a triangular arrangement, it should definitely cover the actual increase. This can only be done for the ratios taken from curves for total losses. Here also we are taking liberties with assumptions and perhaps further tests will help to establish a more accurate increase in ratio. It may be lower.

Table XII has been computed on the basis of the increase in total losses of 15 per cent for flat or random arrangement as set up in Table VIII for concentric standard stranding.

No attempt has been made to set up ratios for segmental conductors in flat or random arrangement.

The increase in a-c resistance due to random arrangement of conductors in a pipe over the a-c resistance when placed in triangular arrangement indicates that, if feasible, the cables when being drawn into a pipe should be tied together in triangular arrangement, particularly if the length of pull is short, that is, only a few hundred feet. The chance of cables assuming a flat or random arrangement is not too great. The pipe size selected is never large enough to allow a flat arrangement in order to prevent jamming of the cables during the pulling in operation.

Resistivity and Magnetic Properties of the Conduits

As a part of the investigation to determine the amount of extra a-c losses residing in the conduit, it was necessary to measure the d-c resistance of the 6-inch conduit and to make the report complete, all conduits were measured for d-c resistance. Also, the magnetic properties of each size were measured as a matter of record. Table XIII gives the results of both sets of measurements. There is no close agreement for the three sizes of conduit for resistivity, and the 6-inch steel pipe seems to have a higher resistivity than the conduits. There is not a great deal of difference in the magnetic properties of the conduits and steel pipe. What variations in the resistivity and magnetic properties occur are not important as the losses in the pipe and conduit only amount to 10 per cent of the total losses, and a variation of only 2 or 3 per cent in total losses.

To complete our records on the characteristics of the materials used, the American Steel and Wire Company and John A. Roebling's Sons Company, through the courtesy of J. J. Morrison and A. P. Bellis respectively, determined the chemical composition of each of the pipes used, as shown in Table XIV.

The chemical composition of the conduit does not differ greatly except that the phosphorous content of the 4-inch conduit is quite high, whereas for the other conduits it is low. In the case of the steel pipe, the copper and silicon contents are about ten times their respective values for conduits.

This research has provided means for calculating the effective a-c resistance of conductors in magnetic pipes (Tables VIII, IX, and X). Assumptions have been made regarding the amount of loss in the pipe so that it is possible to assign to the conductor an effective a-c resistance which, when multiplied by the square of the current, gives a loss at the conductor to which can be multiplied the thermal resistance of the cables inside the pipe to give the temperature drop between the conductors and the pipe. Multiplying the total effective a-c resistance by the square of the current gives the total loss which, if multiplied by the surface thermal resistance of the conduit, will give the

Table XIV. Chemical Composition of Steel Pipes

Diameter of Pipe	Conduits 4 Inches A	4 Inches R	5 Inches A	5 Inches R	6 Inches A	6 Inches R	Steel 6 Inches A	Steel 6 Inches R

A—American Steel and Wire Company tests. R—John A. Roebling's Sons Company Tests.

temperature drop of the conduit. In the case of a buried pipe, this total loss, multiplied by the thermal resistance of the earth, will give the temperature drop of the pipe to earth.

It is recognized that liberties have been taken in making assumptions. It is felt, however, that they are not so broad as to cause serious error in the desired result, namely, a method for determining the total power loss due to current flowing in conductors installed in steel pipes. It is hoped that anyone who is investigating this subject will furnish any data that they have obtained to the committee and perhaps later it may be possible to revise our recommendations.

Appendix. Empirical Method for Calculating the Apparent A-C Resistance of Three Single Conductor Cables in a Steel Pipe

The following empirical method for calculating the apparent a-c resistance of three single-conductor cables in a steel pipe consists (a) in determining the skin effect and proximity effect for the conductors in air by means of the Arnold formula; (b) compute the skin effect, also by means of the Arnold formula for skin effect; (c) subtract (b) from (a), which gives the proximity effect in air; (d) calculate a factor which is a function of conductor diameter, spacing of conductors, and inside diameter of pipe; (e) multiply this factor by (c) to get the proximity of the cable in the pipe. If the skin effect, the proximity effect of the cable in the pipe, and the d-c resistance are added together, we get the total apparent a-c resistance of the conductors. The loss in the pipe is also determined by an empirical formula and is expressed as an increase in resistance. If this latter resistance is added to the skin effect and the proximity effect of the cables in the pipe, the total effective increase in resistance assumed as manifested at the pipe is obtained, which, when added to the d-c resistance, gives the apparent effective a-c resistance external to the pipe.

Table XV

Values of $f(x)$, $a(x)$, $b(x)$, and $c(x)$ for Various Values of x

x	$f(x)$	$a(x)$	$b(x)$	$c(x)$
0	1.0	0	0	0.090
0.25	1.0	0	0	0.090
0.50	1.0	0	0	0.090
0.75	1.0	0.013	0	0.082
1.00	1.005	0.030	0	0.060
1.25	1.014	0.080	0	0.009
1.50	1.028	0.136	0	0.008
1.75	1.047	0.222	0.008	0.042
2.00	1.080	0.322	0.024	0.072
2.25	1.109	0.415	0.040	0.080
2.50	1.175	0.500	0.055	0.085
2.75	1.240	0.568	0.067	0.112
3.00	1.318	0.614	0.070	0.150
3.25	1.403	0.644	0.067	0.200
3.50	1.475	0.668	0.054	0.266
3.75	1.586	0.684	0.043	0.334
4.00	1.683	0.696	0.040	0.411

It is to be noted that this method is entirely empirical and that the constants were so chosen as to tend to follow the trend indicated by the few measurements of the Electrical Testing Laboratories series that were made with varying spacings between conductors or varying pipe size.

The calculation of skin effect and proximity effect of two insulated conductors spaced a distance S apart in air may be found by means of formulas developed by Doctor A. H. M. Arnold.[5] He uses in his formula a constant k as a correction factor for the stranding of a conductor. This factor may vary with degree of stranding and whether strands are clean, oxidized, dry or oiled, and ranges from $k = 0.45$ to 0.90. In this method $k = 1$ is taken.

Skin Effect

If

R = d-c resistance of conductor in ohms per kilometer
R' = a-c resistance of conductor in ohms per kilometer
f = frequency of alternating current in cycles per second
R'/R = skin effect ratio

Then

$$x = 0.01\sqrt{\frac{8\pi f}{R}} \tag{1}$$

$$R'/R = f(x)$$

which is a function of x as given in Table XV in column marked $f(x)$

If

$f = 60$ cycles and R_{dc} is the resistance per thousand feet at the desired temperature of conductor, then

$$x = 0.215/\sqrt{R_{dc}}$$

Skin Effect and Proximity

If

R'' = a-c resistance due to both skin effect and proximity effect for the cables in air
$\alpha = d/S$ = ratio of diameter of conductor to spacing (center to center) between conductors
$a(x)$, $b(x)$ and $c(x)$ are Bessel functions of x,

Then

$$R''/R = \frac{f(x)}{\sqrt{1-\alpha^2 a(x) + \frac{\alpha^4 b(x)}{1-\alpha^2 c(x)}}} \tag{2}$$

$a(x)$, $b(x)$ and $c(x)$ may be found for various values of x up to 4.0 (in Table XV).

Calculate the actual value of skin effect (ohms per thousand feet) by means of equation (1) and skin effect and proximity effect (ohms per thousand feet) by means of equation (2) and then subtracting equation 1 from equation 2 we get the proximity effect (ohms per thousand feet) alone. Call it

$$P_a \tag{3}$$

Proximity effect due to pipe (concentric stranding)

S = spacing (center to center) between conductors, inches
p = inside diameter of pipe, inches
d = diameter of conductor, inches
F = factor to multiply proximity effect in air by to get proximity effect in pipe

$$F = \frac{4.2\,S^3}{pd^2}$$

Then

P_p = increase in resistance due to proximity effect with cables in pipe in ohms per thousand feet

$$P_p = FP_a \tag{4}$$

Increase in resistance due to pipe in ohms per thousand feet

$$PL = 0.00150\frac{S^3}{p} \tag{5}$$

Total effective a-c resistance at conductor in ohms per thousand feet

$$R_{acc} = R_{dc} + \text{skin effect} + FP_a$$

Total effective a-c resistance at pipe in ohms per thousand feet

$$R_{acp} = R_{acc} + PL$$

To use these resistances in order to determine the allowable current in a cable, multiply the total thermal resistance per foot of the cable inside the conduit or pipe by R_{acc} and the external thermal resistance per foot of the conduit or pipe by R_{acp}. Take the sum of both products and divide the allowable temperature rise of the conductor by this summation. Take the square root of the quotient, and this will be the allowable current. The internal and external thermal resistances should be expressed in terms of a single cable.

Example on How to Use Formulas

Calculate the apparent a-c resistance of a 1,000,000-circular-mil conductor having an 0.250-inch wall of insulation with a covering (tape or braid or neoprene jacket) which gives an added thickness of 0.065-inch; (a) at the conductor and (b) at the pipe.

Assume standard concentric stranding

$d = 1.152$ inches = conductor diameter
$2t = 0.630$
$S = 1.782$ inches = spacing of conductors center to center

If it is assumed that the cables occupy 40 per cent of the inside area of the pipe, then the inside diameter of the pipe $p = S\sqrt{7.5} = 2.74S$ inches. Actually the next larger standard pipe size would be used. In determining the calculated ratios given in the report, the actual diameter based on the 40 per cent area was used, otherwise the values of R_{ac}/R_{dc} for various conductor sizes would not lie on a curve.

$p = 2.74 \times 1.782 = 4.88$,
$\alpha = d/S = 1.152/1.782 = 0.646$
$\alpha^2 = 0.418$; $\alpha^4 = 0.175$
$S = 1.782$; $S^3 = 3.18$; $S^2 = 5.67$
$d = 1.152$; $d^2 = 1.328$
$R_{dc} = 0.0108$ ohm per thousand feet at 25 degrees centigrade

Assume conductor temperature to be 70 degrees centigrade

$$\Delta R = 0.00385 \times 45 \times 0.0108 = 0.00187$$

$$R_{dcm} = 0.0108,$$

$$R_{dcu} = 0.01267$$

$$\sqrt{R_{dcu}} = \sqrt{0.01267} = 0.1125, \text{ ohms per thousand feet}$$

From Table XV

$f(x) = 1.065 = R'/R =$ Skin effect ratio

$a(x) = 0.285;\ b(x) = 0.019;\ c(x) = 0.065$

$$\alpha^2 c(x) = 0.418 \times 0.065 = 0.027$$

$$1 - \alpha^2 c(x) = 0.973$$

$$\alpha^4 b(x) = 0.175 \times 0.019 = 0.0033$$

$$\frac{\alpha^4 b(x)}{1 - \alpha^2 c(x)} = \frac{0.0033}{0.973} = 0.003$$

$$\alpha^2 a(x) = 0.418 \times 0.285 = 0.119,$$

$$1 - \alpha^2 a(x) + \frac{\alpha^4 b(x)}{1 - \alpha^2 c(x)} = 1 - 0.119 + 0.003$$

$$= 0.884$$

$$\sqrt{0.884} = 0.940$$

$$R''/R = 1.065/0.940 = 1.130$$

(R''/R is ratio for skin effect plus proximity in air.)

$$R'' - R = 0.130 \times 0.01267 = 0.00165$$

= skin effect + proximity in air

$$R' - R = 0.065 \times 0.01267 = 0.00082$$

= skin effect, ohms per thousand feet

$$P_a = 0.00083$$

= proximity in air, ohms per thousand feet

$$P = \frac{4.2S^3}{pd^2} = \frac{4.2 \times 5.67}{4.88 \times 1.328} = 3.68,$$

$$P_p = F \times P_a = 0.00083 \times 3.68 = 0.00305 \text{ ohms per thousand feet}$$

$$PL = 0.00150 \frac{S^3}{p} = \frac{0.00150 \times 3.18}{4.88} = 0.00098$$

ohms per thousand feet

$$R_{dc} = 0.01267$$

Skin effect $= 0.00082$

$$P_p = 0.00305$$

$R_{acc} = 0.01654$ ohms per thousand feet

$$PL = 0.00098$$

$R_{acp} = 0.01752$ ohms per thousand feet

$$R_{acc}/R_{dc} = \frac{0.01654}{0.01267} = 1.31$$

$$R_{acp}/R_{dc} = \frac{0.01752}{0.01267} = 1.38$$

The tabulation in text gives 1.32 and 1.41 respectively.

Discussion

L. F. Roehmann (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): The discussion of Wiseman's paper will be confined to concentric-stranded cables. This work can be divided into three groups:

1. Single-phase loops in air.
2. Three conductors 3-phase, triangular or flat, in air.
3. Three conductors 3-phase, triangular or flat, in magnetizable conduit.

Group 1 is, of course, easily amenable to calculation and, as expected, measured and calculated values check very well.

Group 2 is amenable to calculation also, but such calculations have been omitted. Figure 1 of the discussion shows calculated a-c/d-c resistance ratios for three single conductors in air, sizes 750,000 to 2,500,000 circular mils, energized with 3-phase current 60 cycles per second, 75 degrees centigrade conductor temperature, flat arrangement, as a function of spacing. These data were calculated by A. C. Connell of our organization from Arnold's formulas. If during the tests in air the three conductors had been arranged flat (instead of cradled), and if the spacing had been varied systematically a direct check would be possible. Even now, it is still possible to calculate from the Arnold formulas the a-c/d-c resistance ratios for the triangular arrangements which were tested in air, and to compare them with the measured values.

Figure 1. 60 cycles per second a-c/d-c resistance ratio at 75 degrees centigrade, 3-phase, flat spacing, Class "B" concentric tinned cable, average for three conductors

Group 3 due to its complexity seems to defy calculation at first sight. However, Atkinson and Wiseman have developed empirical formulas which are quite sim le and which permit calculation of conductor plus pipe losses with an accuracy which is sufficient for practical purposes. This is, indeed, quite an achievement, and the authors should be congratulated.

The question which the discusser asks, without answering it, is this: will the formulas given by Arnold in 1941[1] permit a calculation of this group also? In other words: was this new effort justified, or could Arnold's semiempirical formulas (for the "armouring effect in cables with magnetic armouring") have accomplished the same end? Arnold's formulas show an amazingly high degree of accuracy compared with measurements, usually within one per cent, but his formulas are rather cumbersome. The Atkinson-Wiseman corrections are extraordinarily simple but less accurate. How will Arnold's formulas check the Electrical Testing Laboratories findings for three cables in magnetizable conduit?

L. Brieger (Consolidated Edison Company of New York Inc., New York, N. Y.): For the calculation of 3-phase resistance of cables in air, Wiseman uses Arnold's single-phase formula,[1] even though Arnold also published two formulas for the 3-phase system. One of these is to be found in the paper Eddy Current Losses in Multi-core

Table I

Cable Size, Thousand Circular Mils	Spacing, Inches	At 20 Degrees Centigrade $x = 0.215$ $\alpha = d/D$	$\sqrt{R_{dc}}$	μ	Formula (a) p_s	p_p	$\frac{R_{ac}}{R_{dc}}$	Formula (b) P_1	q_t	$\frac{R_{ac}}{R_{dc}}$	Curtis' Formula $\frac{R_{ac}}{R_{dc}}$ Single Phase
750	1.324	0.752	1.82	0.14	1.054	0.117	1.17	1.133	1.031	1.17	1.12

Paper Insulated, Lead Covered Cables, Armored and Unarmored, Carrying Balanced 3-Phase Current.[3] The second formula of Arnold's will be seen in the paper, Proximity Effect in Solid and Hollow-Round Conductors.[3] The working formulas for the 3-phase system will be found on page 354 of the last mentioned publication, the resistance ratio for three phase being given as the product of two factors. The first is the single-phase proximity factor which is the one which Wiseman uses and the second factor is a multiplier for three phase. Arnold gives factors for triangular as well as flat spacing.

Arnold's 3-Phase Formulas for AC/DC Resistance Ratio

Formula (a),[3] page 55

$$\frac{R_{ac}}{R_{dc}} = p_s + p_p \quad p_s = \text{skin effect factor} = f(x)$$

$$p_p = 3\,\phi \text{ proximity effect factor}$$

$$= \frac{3}{2}\,\alpha^2 G(x)/\{1 - 5/24\alpha^2 H(x)\}$$

$$\alpha = d/D$$

the functions f, G and H are tabulated by Arnold.

Formula (b): $\frac{R_{ac}}{R_{dc}} = q p_1$,

where

p_1 = single-phase factor including skin and proximity effects.

$$= \sqrt{\frac{f(x)}{1 - \alpha A^2(x) + \frac{\alpha B^4(x)}{1 - \alpha C^2(x)}}}$$

q_t (for triangular spacing)

$$= 1 + \frac{1}{4}\mu \frac{5}{24}\mu^2 - \frac{3}{8}\mu^3$$

q_f (for flat spacing) $= 1 + \frac{1}{4}\mu - \frac{1}{8}\mu^2 + \frac{5}{24}\mu^3$

$\mu = \alpha^2 A(x)$; the other symbols are the same as Wiseman's.

These formulas assume that the interstrand resistance correction factor $K = 1.0$, which represents perfect contact between strands.

The effect of the multiplying factor q is significant for large cables at close spacing as indicated by Table I of the discussion.

Wiseman reports good agreement between the test results and Arnold's single-phase formula. But as the 3-phase formulas, would have given higher values, it may be inferred that the correction factor K, which Arnold uses to take into consideration, the effect of interstrand

Table II

Cable Size, Thousand Circular Mils	Spacing, Inches	20°C	70°C
750	1.324	0.93	0.93
1,500	1.7	0.85	0.9
2,500	2.17	0.72	0.81

resistance of the cables upon the proximity effect and which Wiseman assumes to be 1.0, should actually be taken as less than unity. If we assume that Arnold's 3-phase formulas are basically correct and that differences between tests and calculations may be viewed as due to contact resistance between strands, the following values of K would bring the tests and calculations into numerical agreement, as shown in Table II of the discussion.

On the subject of interstrand resistance of dry and impregnated cables clarification is necessary. In the paper presented by Salter, Shanklin and Wiseman,[4] it is implied that impregnation reduces the proximity effect, hence the interstrand resistance is larger for impregnated cables. Arnold on the other hand reports that the contact resistance between strands is greater for dry than for impregnated cables and that even for impregnated cables it does not exceed 0.8. Wiseman's committee would do a good service by clearing up this contradiction.

Before leaving the subject of theoretical formulas, I wish to draw attention to a paper written by H. L. Curtis, in 1920.[5] Curtis derived a power series expression for the ac/dc resistance of a single-phase circuit. This series is laborious to evaluate, but he has checked his method by tests on number 2 copper wires at various spacings and at frequencies up to 3,000 cycles. Curtis' formula agrees with Arnold's, and with all others which have been developed, in the substantial principle that the resistance ratio in air is a function of only two parameters: (1) the ratio of frequency and d-c resistance per unit length (f/R_{dc}), and (2) the ratio of conductor diameter to spacing between centers (d/D).

Curtis' data can, therefore, be readily recalculated for all practical conductor sizes at 60 cycles. This was done, and the data are plotted on Figure 2 of the discussion. The agreement with Arnold's single-phase formula may be judged by reference to Table I of the discussion. It would be simple to plot curves for 3-phase flat or triangular arrangement by using Arnold's multipliers, thus obviating the need for calculations so long as a single frequency is involved. More will be said about Curtis' studies in connection with reactance.

Table III

Arrangement	Conduit	R_{ac} at 25 Degrees Centigrade, Ohms Per 1,000 Feet	R_{ac}/R_{dc}
Triangular	4-Inch fibre	0.0153	1.095
Triangular	4-Inch iron	0.0162	1.16
Flat	5-Inch fibre	0.0154	1.10
Flat	5-Inch iron	0.0168	1.20

In addition to the foregoing remarks as to procedure, a few comments are submitted on the numerical data in the paper.

The comparative resistance ratios for 750,000 and 2,500,000-circular-mil concentric-strand conductors in triangular and flat configurations require critical review. I share Wiseman's suspicions regarding the data on 750,000-circular-mil cables. As a substitute, results of tests made on 750,000-circular-mil rubber-insulated low-voltage cables ($D = 1.475$ inch spacing) by the Consolidated Edison Company of New York, will be seen in Table III of the discussion.

The a-c resistance in air is practically the same for triangular and for flat arrangement which is consistent with Arnold's theoretical data.

The Electrical Testing Laboratories' tests on 2,500,000-circular-mil cables look better, although the values are not quite in agreement with theory. As Arnold reported good agreement between tests and calculations for flat arrangement, his 3-phase multipliers may be accepted as a basis of discussion. Table IV of the discussion is instructing because it shows the range of changes which may be expected theoretically.

Table IV

μ	q_t	q_f	q_f/q_t
0.2	1.042	1.045	1.0
0.4	1.066	1.081	1.014
0.5	1.072	1.095	1.023
0.6	1.019	1.100	1.037
0.8	1.004	1.155	1.155
1.0	0.667	1.334	2.0

It is interesting that the multiplier for triangular disposition reaches a maximum and ultimately becomes less than 1.0 which means that for large conductors very close together, the 3-phase resistance may be smaller than the single-phase resistance. The ratio of flat and triangular arrangement increases continuously with increasing cable size and decreasing spacing, although the increase is rather slow until large conductor sizes are reached. For the 2,500,000-circular-mil cables on the Electrical Testing Laboratories' test $\mu = 0.48$ (see Table I of the discussion) and the flat arrangement offers about 2.3 per cent greater resistance than the triangular assembly. Wiseman's reports the increase as 4.6 per cent at 20 degrees centigrade and 8.5 per cent at 80 degrees centigrade. If theory means anything, the ratio between flat and triangular disposition should decrease with temperature.

In reference to Table VIII of the paper which contains the ac/dc resistance ratios

Figure 2. Chart based on Curtis' formulas

for cables in pipe, tests made by Consolidated Edison Company on rubber-insulated low-voltage cables are submitted for comparison with the data in the table for the first three conductor sizes listed. The tested R_{ac}/R_{dc} at 25 degrees centigrade were as shown in Table V of the discussion.

Table V

4/0 triangular—1.03 in 3-inch iron pipe
500,000-circular-mil triangular—1.075 in 3-inch and 4-inch iron pipe
750,000-circular-mil triangular—1.13 in 4-inch iron pipe

These figures are lower than Wiseman's in spite of the low temperatures of the Consolidated Edison Company test. Perhaps interstrand contact resistance is raising its ugly head.

The 15 per cent over-all increase for flat or random disposition in pipes over triangular arrangement in pipes may be satisfactory for large cables, but it is too much for the smaller conductors. This is indicated by the comparison in Table VI of the discussion between laboratory and field measurements on 500,000-circular-mil cables. (The data below are based on the writer's paper, "Impedance of 3-Phase Secondary Mains in Non-metallic and Iron Conduits.")[6]

Table VI

Laboratory Tests	$\frac{R_{ac}}{R_{dc}}$	
Triangular in 4-inch fibre conduit	1.03	Ratio: 1.10
Triangular in 4-inch iron conduit	1.075	
Flat in 4-inch fibre conduit	1.03	
Flat in 4-inch iron conduit	1.105	
Field Tests		
Random disposition in 4-inch fibre conduit	1.055	
Random disposition in 4-inch iron conduit	1.185	

In view of the smaller values in Table V of the discussion and the lower correction factor for randomness brought out by Table VI, a downward revision of the figures in Table XII of the paper is indicated at least for the 250,000-, 500,000-, and 750,000-circular-mil sizes.

F. H. Buller (General Electric Company, Schenectady, N. Y.): Though I am not a member of the Insulated Power Cable Engineers Association committee which was responsible for the work reported by Wiseman in his paper, I have had the privilege of being associated with this committee ever since the work started, and it is my opinion that the Electrical Testing Laboratories have done a fine piece of work in obtaining the data presented in Wiseman's report. While it is evident that the work as it stands is not complete (particularly in the field of segmental cables) nevertheless the data reported by the author represent an important contribution to our knowledge of a-c losses in cables in magnetic pipes; and it is to be hoped that additional data will become available in the future to supplement those in this paper, and to fill out the gaps therein, the existence of which Wiseman fully and properly admits.

A few additional comments are in order. The author states that the skin effect observed on the 2,500,000-circular-mil segmental cable tested in air agrees well with the 44 per cent rule. The General Electric Company has always used a 50 per cent rule, based on a variety of test data from several sources. Here is how the data compare:

Source of Data	Skin Effect	Remarks
Electrical Testing Laboratories	1.12	Test
44 per cent rule	1.11	Calculated
50 per cent rule	1.14	Calculated

This test indicates clearly that, while the 44 per cent rule gives a closer approximation to the test than the 50 per cent rule in this case, it is nevertheless not on the safe side; and, on the basis of this one test it does not appear advisable to us to depart from the 50 per cent rule.

Skin effect in air, as reported from the Electrical Testing Laboratories tests, appears to agree very well with the handbook data; however, the agreement between the test data on total losses on cables in the pipe and Atkinson's empirical formula is not at all impressive (see Table VII of the paper). This empirical formula as it stands should be used with the greatest caution in attempting to extrapolate the test results.

It is in fact rather surprising that almost one-third of the author's paper, is devoted to an empirical formula which gives results as erratic as Atkinson's. To do that gentleman justice, however, the pages devoted to the formula do not all represent wasted space; the Arnold proximity effect formula for cables in air, while well-known in England, is not nearly as widely publicized as it should be on this side of the Atlantic. In presenting this formula, Atkinson has done the industry a service.

It would be very desirable to obtain additional data on random-arranged cables. Some engineers contend that triangular arrangement is automatically obtained when three cables are pulled into a pipe simultaneously (or hexagonal arrangement when there are six). They base their opinion on the observed fact that the cables are twisted together as they leave the pipe. If, however, this opinion were correct, the cables would be completely transposed every few feet in the pipe, and their reactances to neutral would be identical. Field tests show clearly that these reactances vary widely, in actual practice. Hence the twisting must be confined to a relatively short length at the pulling end of the cables. We are told also that this conclusion is borne out by certain mechanical investigations which have been made in the field. It would thus appear that random arrangement rather than triangular arrangement actually prevails in practical cable lines.

It should be noted that the tests reported by Wiseman did not involve shielded cables, or cables with pulling armor (skid wires). Such skid wires and shields contribute materially to the losses in the system where conductor sizes are large; tests are now underway to determine their magnitude exactly, and to check it against theory. Results to date indicate clearly that such losses are large enough to increase over-all a-c losses considerably above the values obtained on the Electrical Testing Laboratories tests, where large conductors are involved. It is expected that the results of these tests will fill yet another gap in the present report.

E. S. Halfmann (Philadelphia Electric Company, Philadelphia, Pa.): Wiseman's paper presents much valuable data in a field where virtually no published information exists. It is unfortunate, however, that the test program was not extended to cover certain additional factors which would be extremely useful to the users of large size cables. Two examples will be given.

The first is the effect of compact segmental stranding on the a-c/d-c ratio for different sizes of conductors. Since tests on only one cable of segmental construction have been reported, it is not possible from data supplied in this paper to determine the variation of the a-c/d-c ratio with conductor size. In cables of segmental construction, the a-c/d-c ratio is probably also affected by the shape of the individual segments and by the number of segments insulated. Compact-segmental stranding is now used exclusively by the Philadelphia Electric Company for paper- and varnished-cambric-insulated cables in sizes larger than 1,000,000 circular mils, and hence the importance of this factor can readily be seen.

The second factor is the introduction of additional heat loss due to the presence of metallic shielding tapes, reinforcing tapes and skid wires which are normally used on pipe-type cables. No outer conducting tapes were used on any of the test cables. Experience indicates, however, that considerable additional loss can be introduced by these outer tapes, the exact magnitude of this loss depending on the particular taping construction used by the individual manufacturer. Results of tests on samples of 2,000,000-circular-mil compact segmental pipe-type cables, made and tested for us by two manufacturers, indicate a-c/d-c ratios of 1.86 and 1.98 at 60 degrees centigrade. These values are considerably higher than Wiseman's figure of 1.79 on an even larger size of cable (2,500,000-circular-mil) without metallic taping.

These examples serve as a warning that extreme care must be exercised if the expected advantages of very large conductor sizes are not to be lost because of unexpected additional losses in the conductors and in the metallic tapes.

M. H. McGrath (General Cable Corporation, New York, N. Y.): The paper by Wiseman is without doubt a contribution that will be of interest and value to cable engineers everywhere in connection with problems relating to the current rating and voltage drop of large-size conductors installed in steel conduit. When the research program covered by this paper was initiated prior to the war, primary emphasis was being placed on the need for resistance and reactance data of nonleaded low-voltage cables with rubber, rubber-like or varnished-cambric insulation installed in steel conduit in power stations or industrial plants.

Since the war, there has been a great increase in the use of impregnated-paper insulation in pipe-type systems for high-voltage transmission feeders. As a result, the present-day need for detailed knowledge of the many factors influencing the a-c losses of large size conductors in steel conduit, far transcends in economic importance anything one might have had reason to believe would be the case at the time the program was initiated. It would appear, therefore, that there is need for new material, new advice on this all important phase of high-voltage cable.

The data given demonstrates that the placement of a steel pipe about a 3-phase cable group, not only produces an extra a-c loss in the steel of the pipe itself, but in addition, may very materially increase the loss actually generated in the conductors. In the past, this point has received little, if any, attention in the technical literature. Investigators have invariably merely reported the over-all difference in a-c/d-c ratio with and without the pipe in place, thus giving no indication as to relative proportions of the extra loss developed separately in pipe and conductor.

The effective calorimetric method described in the paper removes our knowledge of the distribution in question from the unsatisfactory "conjecture" category existing in the past to one in which the distribution can now be expressed in numbers. As invariably happens in such cases, it can be confidently expected that the ability to obtain numerical knowledge of the distribution will lead to the development of refinements in existing conductor designs which will reduce the loss occurring therein.

For cable applications in station areas or in industrial plants, the data presented also provides a relatively accurate means of determining the gain to be obtained by use of nonmetallic fibre or transite conduit in place of steel for 3-phase groups, and also permits a more accurate evaluation than has been practical in the past, of the improvement with cables installed in separate nonmetallic ducts in place of a single conduit. These comparisons were made possible by the inclusion in the paper of the test data for both "in air," as well as the "in pipe," cases.

The relatively large difference in absolute magnitude of both the "in air" and "in pipe" values reported for the 2,500,000-circular-mil conventional concentric strand as compared to the corresponding values for the same size compact-segmental strand, indicates that when cables are installed as a 3-phase group in contact with one another, a check of the relative improvement possible with low skin-proximity effect designs such as annular or segmental will be justified, particularly whenever conductor sizes of about 1,000,000-circular-mils or larger are involved.

Furthermore, the approximate, but nonetheless entirely adequate relationship between the "in pipe" a-c/d-c ratio and temperature established in Wiseman's paper will in many cases permit a worthwhile improvement in the accuracy of current rating calculations, particularly where the higher a-c/d-c ratios are involved. In the past, lack of appreciation of this relationship has often necessitated the employment of laboratory room temperature measurements without correction to allow for the decrease at maximum permissible copper temperature. As shown in Wiseman's paper, there may be an appreciable difference in the two values.

The General Cable Corporation has for some time been conducting an extensive series of ac/dc measurements relating primarily to high-voltage pipe-type cable, and it is anticipated that the results of this investigation will be available for publication in the near future.

C. T. Hatcher (Consolidated Edison Company of New York, Inc., New York, N. Y.): The members of the Insulated Power Cable Engineers Association under the chairmanship of Wiseman are to be commended for their efforts to add to our knowledge of the a-c resistance of power cables. In view of the expansion in recent years of the high-pressure pipe-cable systems, our interest in the a-c resistance of cables in steel pipes also has necessarily increased.

A. H. M. Arnold's papers on the a-c resistance of power cables present useful tools in calculating the a-c resistance of such cables in air. The subject of a-c resistances in pipe has received considerably less attention and the present Insulated Power Cable Engineers Association data are, therefore, particularly welcome.

Unfortunately for some of us interested in high-pressure pipe-cable systems, Wiseman's paper necessarily will be an Interim Report. The known high a-c resistance of standard concentric stranding in cable sizes above 750,000- or 1,000,000-circular-mils precludes the economic use of such stranding, especially as the desired capacity of proposed extra high-voltage circuits may require the largest practicable conductor sizes. This situation presents itself also in lower voltage circuits in which lesser power requirements, nevertheless, at the lower voltages, may still mean copper sizes in the 1,500,000- to 3,500,000-circular-mil range. Here again, because of known relatively high a-c resistance, concentric stranding has generally been abandoned in favor of, first, rope core conductors and later, the segmental conductor design.

The Consolidated Edison System has only a limited amount of low-voltage concentric cable above 750,000-circular-mil size installed three per pipe. More generally, such cables are installed one per nonmetallic duct with sheath loss suppression methods in effect, leaving skin effect and to some extent proximity effect as resistance factors of interest. Generator cable leads of older vintage are of the rope-core type. The more recent installations, where not metal-clad, are of segmental conductor design. Either rope-core or segmental-type are, however, installed one per duct in sizes above 1,000,000-circular-mils.

Our interest in the Consolidated Edison System in large size power cables installed in steel pipe is confined primarily to extra high-voltage high-pressure pipe cable systems. Of this type, three circuits are now in service at 138 kv, comprised as follows: approximately 5 miles of 350,000 circular-mils (concentric); and 16 miles of 1,500,000 circular-mils (segmental). Approximately 22 miles of 1,500,000-circular-mil segmental conductor circuits are authorized and scheduled for service in 1950.

It is appreciated that the tests initiated by the Insulated Power Cable Engineers Association were not intended primarily for high-pressure pipe circuits, as the major emphasis in these tests is on concentric-stranded conductors. It is fortunate that the appropriation fund allowed tests on at least the 2,500,000-circular-mil size.

Table VII. Comparison of A-C and D-C Resistance-Field Tests—Random Spacing

	Test at 20 Degrees Centigrade Total Resistance, Ohms				Computed at 70 Degrees Centigrade (Myerhoff Method) Total Resistance, Ohms			
	A-C	D-C	Difference	Ratio	D-C	Difference	A-C	Ratio
Circuit A	0.527	0.284	0.243	1.86	0.340	0.243	0.583	1.72
Circuit B*	0.488	0.288	0.200	1.69	0.345	0.196	0.541	1.57
Avg								1.64

* The data of test "B" was taken originally on a circuit of pipe-cable plus oil-filled cable in series. Values for the pipe-cable portion of the circuit alone were derived using other test data for the oil-filled cable portion of the circuit.

Additional test data on, say, a 1,000,000- or 1,500,000-circular-mil segmental cable made under the same test conditions would have been particularly welcome. As Wiseman reports, tests have or are being made on several other conductor sizes and this data will be of great interest to the industry. These tests, at least in part, will be on impregnated cables and it is essential that the effect of dry versus oiled stranding be resolved.

The Consolidated Edison Company has recently completed field tests on two 8-mile pipe circuits of 1,500,000-circular-mil segmental cables. The results of these tests have not been completely analysed but the data shown in Table VII of the discussion are presented to illustrate the level of a-c/d-c resistance ratio obtained on field installations with random spacing.

The test results given in Table VII of the discussion are based on field measurements made without the precise degree of control exercised in the Electrical Testing Laboratories test. The results are, however, believed to be correct within a few per cent. The cable of both circuits is installed in $8^3/_8$-inch outside diameter pipe. The insulation is 560 mils and although the cable of each circuit was furnished by a different manufacturer, the designs are generally similar, differing only slightly in some repects as to cable makeup. Additional test data will be made available to the industry as authorized lines are installed. The average a-c/d-c resistance ratio of 1.64 at 70 degrees centigrade obtained for the two tests listed in Table VII appears rather high in comparison with some laboratory test values which have been presented to us for triangular spacing.

W. A. Sinclair (The Detroit Edison Company, Detroit, Mich.): Del Mar, Salter, Wiseman, and the Insulated Power Cable Engineers Association have made a very valuable contribution to the data required for determining ratings of pipe-type cables. The a-c resistance of large size conductors in steel pipe has been a very controversial subject and requires settlement if this type of cable is to be operated economically.

Results of a series of tests conducted on the 35,130-foot Delray-Warren line of the Detroit Edison System provide an excellent opportunity to check the tables set up in this paper for flat or random spacing. This 120-kv high-pressure gas-filled cable line consists of three *SMD*-type single-conductor cables installed in a $6^1/_2$-inch inside diameter by $^1/_4$-inch wall, mild steel pipe. The 600,000-circular-mil concentric-round conductors are insulated with 600-mils preimpregnated paper over which is a bronze tape intercalated with saturated cotton tape, cotton webbing tape lapped, and two half-round copper skid wires 200 by 100 mils applied open spiral, double start. The diameter over the skid wires is approximately 2.315 inches which means that for this particular line 38 per cent of the pipe is occupied.

Before circulating any current in the conductors, the d-c resistance of the total cable was measured by means of a portable Kelvin double bridge. This value, along with measured temperatures, was used as a reference value for all conductor temperature computations.

Test current for the positive sequence impedance measurements was supplied by six 500-kva transformers connected to give an open-circuit phase-to-ground voltage of about 1,290 volts. Table VIII of the discussion shows the impedance values obtained with 530 amperes along with the respective calculated values of resistance and reactance.

Comparing the a-c/d-c resistance ratio values in Table VIII of the discussion to those given in the paper, we find the 1.26 value to be 7 per cent higher than the values given in Table VIII of the paper for triangular arrangement. This would indicate the assumed 15 per cent increase in total losses, due to random arrangement over triangular arrangement of the conductors in a pipe, is on the conservative side.

K. W. Miller (Armour Research Foundation, Chicago, Ill.): For several years I have not been involved in underground cable problems. However, on the basis of past activities, I retain considerable personal interest in them.

On the basis of work which I did many years ago on the resistances and reactances of single conductor 3-phase circuits with various configurations of the cables, I recall that whenever there is departure from equilateral triangular symmetry of the cables themselves or of their inductive coupling with surroundings, then there is introduced a nonequality of impedances of the individual cables. Perhaps it is best to consider these inequalities, as introduced by unequal transformer action between the conductors or phases inasmuch as, if I recall correctly, under some extreme conditions, apparent losses may actually become negative in one phase or conductor. Therefore, it is not surprising that the authors found considerable inequality in impedances of conductors in their tests, where the cables themselves were not strictly equilaterally spaced or the center of the group as a whole was eccentrically located with respect to the center of the pipe or conduit.

Several years ago, it was practice on the Commonwealth Edison System in Chicago to align ducts with thin sheet iron conduit bands to hold them in place while pouring the concrete of the conduit structure around them. Although the total cross-section of magnetic iron surrounding a single conductor in a length of cable from manhole to manhole totaled only a square inch or so, and even this in time rusted away, nevertheless, oscillograph measurements indicated that a large amount of harmonics was introduced into the induced sheath voltages due to the nonlinear magnetic character of these iron bands. Perhaps oscillograph measurements were taken in some of the tests reported by the authors, and if so, it would have been of great interest if the results had been described in one or more of the papers. Personally, I would expect a considerable harmonic content in the resistance and reactance voltage drops even though all three phases are contained inside a single pipe or conduit, because the heavy iron wall of the conduit and the fact that the individual cables are necessarily separated by distances comparable to the radius of the conduit should to a considerable degree make up for the fact that phase summation of currents in a conduit is zero.

I am further unconvinced that resistance and reactance values are actually as independent of current magnitude as is reported. The current values listed in a recent paper[1] by E. H. Salter in Table IV vary by a ratio of only 3 or 4 to 1 at most and, it is important to note, tabulated values start with already sizeable conductor currents. It would seem probable that resistance and reactance values would both increase considerably for much smaller conductor current values, although, of course, the importance of such increase in R or X might not be particularly important, inasmuch as it is the I^2R and IX products which may be of chief concern. On the other hand, it is theoretically evident that as the currents I become indefinitely large, the resistance and reactance values must approach the same values as would exist with the iron conduit or pipe entirely ab-

Table VIII

Test Number	Conductor Temperature, Centigrade	Impedance, Ohms	Phase Angle	A-c Resistance, Ohms per 1,000 Feet	Reactance, Ohms per 1,000 Feet	D-c Resistance, Ohms per 1,000 Feet	A-c/D-c Resistance Ratio
1	11	2.149	68.71	0.0222	0.0570	0.0168	1.32
2	36	2.189	67.41	0.0239	0.0575	0.0185	1.29

(Estimated)	70	2.236	65.58	0.0262	0.0579	0.0208	1.26

sent. I do not question the essential accuracy of the approximate constancy of the data reported, but, in the above remarks, point out that, in general, on theoretical grounds, this may not always be true. Fortuitous convenience of the reported results may be of questionable application where conditions of permeability, conduit, pipe, or cable size, or other geometric ratios are essentially different.

For practical computations on engineering accuracy, however, in a field where precise calculations are virtually impossible, the measured and reported empirical values covering as wide a field as they do, doubtless will be the most helpful, and the authors are to be commended for making these results available.

1. PROBLEMS IN THE MEASUREMENT OF A-C RESISTANCE AND REACTANCE OF LARGE CONDUCTORS, E. H. Salter. AIEE TRANSACTIONS, volume 67, part II, 1948, pages 1390–97.

E. E. Hutchings (British Electrical and Allied Industries Research Association, London, England): The results given in test number 1 in Table I of Wiseman's paper agree well with the theoretical calculation of skin effect, since in this test the spacing is such that proximity effect would be negligible. The additional increment of resistance due to the latter effect in test number 2 is, however, very much greater than would be expected on theoretical grounds at the spacing indicated. Proximity effect for three cables in triangular formation in air, closely spaced, is given to a close approximation by the expression—

$$y_1 = 1.5(d/s)^2 y$$

where

d = diameter of the conductor
s = axial spacing between conductors
y = increase due to skin effect.[1]

The losses in the conductors in air, in the absence of adjacent metalwork, can be measured and compared with theory on well-established principles.[2] Very close agreement has been obtained in tests, similar to those described in the papers, which were carried out by the British Electrical and Allied Industries Research Association.[3] The increase in resistance due to proximity to steel in the form of plates parallel to the conductors is less than 0.002 microhm per centimeter at 12 inches from the steel for closely spaced conductors (as in a pipe) and is independent of conductor size.[4] This is less than 2 per cent for the largest conductors considered in the AIEE papers. The excess losses when the conductors are run in a steel pipe can be compared with theoretical values calculated as for steel armoured cables by known methods[5] using the appropriate properties of the steel. Only an approximate value need be assigned to the permeability, since variation of this over a wide range has but little effect. Unfortunately, only the nominal diameter of the pipes and their resistivities are given in the present papers. Full dimensional data are required in order to check the experimental results against the theory.

A similar investigation to that described in the papers was carried out by the British Electrical and Allied Industries Research Association in 1939[6] and led to the following conclusions:

1. The current rating of two or three single conductor cables is not appreciably affected by running them in steel pipes.

2. The total losses in the steel are in reasonable agreement with those deduced from the theory of armour losses and would be but little affected by the magnetic properties of the steel for ordinary pipes. These losses are substantially independent of the symmetry of the cable system with respect to the pipe, so long as the cables are closely spaced.

3. The volt drop may be materially increased by running cables in steel pipes. This is largely due to the increase in reactance. The increment of reactance will usually be of the order 0.3 microhm per centimeter, in accordance with approximate theory. The impedance was found to be increased by 30 per cent in the worst phase with 0.5 square inch cables due to their installation in a $3^1/_2$-inch diameter steel pipe, approximately 7/32 inches thick.

R. J. Wiseman: We appreciate very much the interest shown in this and the other two[1,2] papers reporting on the study made for Insulated Power Cable Engineers Association by the Electrical Testing Laboratories on large size conductors in conduits or steel pipes.

We would like to state a few facts which we hope will clarify for some of the discussers, views which they have presented. We are fully cognizant that this study is very limited in scope and should have been carried out on a much broader scale. Unfortunately, our funds were quite limited and, therefore, we tried to cover the primary objective as far as it was possible to do. This meant we were concerned with rubber- and varnished-cambric cables more than paper-insulated cables. This accounts for using a dry paper cable. A thin wall of insulation was used as it more closely followed low-voltage cables. However, we did make tests with several spacings of the 750,000-circular-mil conductors to indicate the trend for heavier walls of insulation. We should have had cables with shielding tapes over the insulation, but we did not have the funds to do so. Also it was recognized that such designs were special as far as Insulated Power Cable Engineers Association was concerned. We do regret mostly that only one size of segmental conductor was tested. If we had been able to make tests for several sizes, as for concentric stranding, we might have been able to set up a complete table of a-c/d-c ratios for all conductor sizes as we have done for concentric stranding. Personally, I am using the empirical formula for correcting for proximity effect found applicable for the 2,500,000-circular-mil segmental conductor and tests made on smaller sizes indicate that the a-c/d-c ratio obtained is less than the calculated.

Several have commented on various factors influencing the a-c/d-c ratio, such as temperature, current strength, pipe size, spacing, and so forth. This is all true, but we must keep in mind that it is necessary to set up a tool which is easily applied without too many correction factors to meet the particular conditions for each specific case. If we had to do so, we would never get any work done, so we agreed to set up a single curve for the a-c/d-c ratio which would be close enough to the correct value to be within the accuracy of other factors such as thermal resistivities. This meant that we use a ratio which would be that for a temperature close to the usual cable temperatures, that is, for full current load. We selected the ratio at 70 degrees centigrade as many cables today are operating at this temperature and some above it. For those above 70 degrees centigrade the actual ratio is slightly lower than for 70 degrees centigrade. Therefore, we are conservative. For cable setups operating at less than 70 degrees centigrade the actual ratio is higher than for 70 degrees centigrade. Therefore, the a-c resistance computed will be less than the actual resistance and the current allowable higher than it should be. The error will not be great, but if anyone is actually concerned they can use the empirical formula method for calculating the a-c resistance more accurately.

We realize this research is only partially completed, not over half done, and I hope that we will somehow find funds to carry on this work. It is important to the industry as a whole.

Referring to specific discussions. Answering Miller, we did not make oscillograph measurements during tests. We agree that the wave shape is probably upset. We started our tests at 750,000-circular-mil conductors as we were interested in large size conductors. However, low-current values were used to obtain the influence of temperature on the resistance and reactance. Therefore, we had low-current density. Likewise the highest temperature was slightly over operating temperature, so we had current densities as high as would be expected in service. Going further than this is not necessary for our purposes.

We recognize Halfmann's warning regarding the use of segmental conductors and it is regrettable we did not have the opportunity to make more tests on this conductor design. The variation that he reports on a 2,000,000-circular-mil conductor needs consideration from all the construction variations that may exist between the two designs.

Buller questions the use of the 44 per cent rule for determining the skin effect factor for a segmental cable. This matter was discussed by the Insulated Power Cable

Engineers Association years ago and data was presented by several companies as to what factor should be used. It was agreed to in the Association that the 44 per cent rule had more basis, in fact, than the 50 per cent rule and the former was adopted. The Electrical Testing Laboratories tests made on the 2,500,000-circular-mil segmental cable in air seems to check this decision.

Buller objects to taking too many pages to present the empirical formula proposed by Atkinson. I feel we are indebted to Atkinson for proposing a means for calculating the a-c/d-c ratio for any conductor size. To me, we took just as much liberty in plotting a curve and then taking from its ratios for any conductor size when we actually had only six points and four of these were for the same conductor size; therefore we really plotted a curve with three points. What I like about Atkinson's empirical formula is that it gives us a picture of what may be the proportional of increased resistance due to proximity and the presence of the pipe. We do not claim the empirical formula to be the last word, but it is surely better than anything to date that we have. In view of its newness it was necessary to discuss it in detail; therefore, it took a large number of pages to present it. I take full responsibility for this. I do not consider the values obtained by the empirical formula as erratic. Considering the cable construction that we are dealing with, I think it is remarkable that a simple formula was found which could be used practically and does check actual tests. We are not looking for an accuracy of 0.1 per cent. We are glad to know if we are as near as 1 per cent.

We agree with Buller that further information is needed on random arrangement of cables in a pipe. There are strong views both ways as to how cables are positioned when drawn into pipes. Therefore, it is best that we leave it to further installations before we draw any final conclusions.

We like very much the manner in which McGrath has described the over-all picture as to the necessity of having the true a-c resistance and reactance of cables in steel pipes. We wish to state that McGrath materially helped the committee in the study of the test data and contributed very constructive comments in interpreting the results.

The tests reported by Hatcher on the two 8-mile circuits of 1,500,000-circular-mil segmental conductors are very helpful and will be included in the compiling of actual field tests. We agree with Hatcher that the results seem rather high in comparison with laboratory test values which some of us are finding for triangular spacing. It shows the necessity of further investigation.

We are indebted to Sinclair for contributing tests made on the 120-kv high-pressure gas cable in the Detroit Edison Company. Calculation of the a-c/d-c ratio using the empirical formula gives the results shown in Table IX of the discussion. The actual ratio is roughly 5 per cent higher than the computed. This may be due to random arrangement as Sinclair believes or possibly accuracy in measuring the a-c watts.

Unfortunately, time has not been available to devote to further study of this subject along the lines suggested by Roehmann with reference to the use of Arnold's formulas for the effect of armoring on the losses in cables. I believe he has a good point. Knowing Roehmann's interest in this subject, perhaps he or A. C. Connell of Anaconda Wire and Cable Company will take the time to make such calculations for us and report them to the committee for incorporation in the Insulated Power Cable Engineers Association report.

We appreciate the interest that Brieger has taken in this study and his discussion is going to be helpful to all of us who are giving this subject consideration. When we were considering the empirical method for calculating the a-c/d-c ratio, we were acquainted with Arnold's work. Perhaps I should have taken the working formulas for the 3-phase system in air instead of that for the single-phase system, but I looked upon it as a means to an end, that is, we hoped to find a factor which, when multiplied by the proximity effect, would give the proximity when cables were installed in pipe. What it means is that we would have to use the same procedure but the factor would be different according to whether we start with a single-phase or a 3-phase formula, but the end result would be the same. It seems to me as if it is much simpler to use the single-phase formula.

It was intentional when the factor K in the Arnold formula for the interstrand resistance correction was taken as $K=1.0$. This is a variable depending upon the degree of contact between strands, oxidation of surface of strands and whether strands are dry or oiled. All of these will vary according to the manner in which a conductor is manufactured and every time the conductor is made. Brieger gives suggested values which vary with conductor size and temperature. We do not believe it is possible to arrive at a specific value of K; therefore I assumed it to have a value $K=1$. This means that there is this variable present in actual practice and we can not expect accurate check of computed and actual values. We are trying to get as simple a formula as will give a better indication of what a-c resistance we can expect to have when cables are installed in pipes than that which we have had heretofore and be within practical accuracy.

Reference to Curtis' work is most valuable and the agreement between P_1 and his values of a-c/d-c ratio shown in Table I of the discussion is quite remarkable. The curves in Figure 1 of the paper could be used instead of going through the calculation by the Arnold formula.

As in the case of having only one test for segmental conductors we only had two tests for flat arrangement. Many more are needed before we can draw more accurate conclusions. The data reported by Brieger in Tables III, V and VI of the discussion indicate that it is necessary to proceed cautiously on the influence of flat or random arrangement and that the 15 per cent factor we have assumed because of the 2,500,000-circular-mil tests is too high. Perhaps we should not go over 10 per cent.

I wish to repeat that the committee recognizes its work is only partially completed. Field tests being reported as pipe-type systems are installed indicate a modification of our conclusions may have to be made. This would be speeded up if it were possible to obtain funds to carry out laboratory studies on various combination of construction as a guide to their influence. This is a long time proposition. It is ideally suited to a university research laboratory for students studying for advance degrees. Can we find a source of funds and a university who will undertake the task?

We are very glad to receive Hutthing's discussion, knowing the interest he has had for many years in losses in power cables.

In no case does the law he gives for proximity in air apply to any of our tests with cables in air in triangular formation. If the factor 1.5 was changed to 2.0 better agreement would be obtained.

I think it worthwhile when time permits to make a comparison of both the Arnold formula for the effect of armoring on the losses in cables and the Booth, Hutchings and Whitehead method.[3] Perhaps Roehmann can make both calculations. We should keep in mind that in the case of armored cables we have the magnetic jacket close to the conductors, whereas for cables in a pipe only where the cables rest on the bottom of the pipe are the conductors and the magnetic jacket close together. This should influence the values found.

We are planning to send to Hutchings the full dimensional data on the pipes so that he can check theory and experimental results.

The conclusions arrived at by British Electrical and Allied Industries Research Association in 1939 are quite interesting. For small conductor sizes the first conclusion is correct, but for large sizes which we are primarily interested in for pipes, there is a decrease in allowable current as compared to cables in duct.

The second conclusion as to total losses can be checked when Hutchings makes a comparison between the theory of armor losses and that which was found on our tests. Reference to the effect of cable symmetry is interesting. We do keep the cables closely spaced because we try to use the smallest pipe size possible in order to hold costs down. It indicates that if random arrangement does take place, the increase should not be great. This also seems to be indicated in the Detroit Edison Company tests.

Table IX. AC/DC Ratio

Test Number	Temperature Degrees Centigrade	Detroit Edison Tests a	Computed b	a/b
1	11	1.32	1.27	1.04
2	36	1.29	1.23	1.05
3	54.5	1.27	1.21	1.05

Causes and Effects of Stray Electric Currents in Coal Mines

L. H. HARRISON
MEMBER AIEE

THE HAZARDS represented by stray electric currents in coal mines and earth strata have been a major problem since electric shot-firing methods were introduced some years ago. The accident records of the mining industry are replete with instances of premature explosions and shot-firing accidents of various kinds for which the only logical explanation is stray or uncontrolled electric currents in the earth.

The sources of these stray electric currents are, in all probability, numerous and varied. It is not the purpose of this paper to enumerate all possible sources; however, two principal sources of such currents in the earth are:

1. Lightning discharges to the surface of the earth.

2. A combination of power circuits and electric equipment used for the normal operation of the mine.

The first source is, of course, one about which little or nothing can be done. The second source is largely preventable, although complete elimination of such currents, even from these sources, is virtually impossible. Certain precautionary measures can be taken, but the effectiveness of such measures can be greatly increased by well-planned electrical installations and proper maintenance.

Some Blasting Accidents Caused by Stray Currents from Power Circuits

An air shaft was being sunk from the surface when a premature blast occurred. The shaft was down about 150 feet and blasting was done electrically and fired from a 250-volt power circuit. The men were hoisted and lowered in a metal bucket which was moved by means of a d-c motor-driven electric hoist. A round of holes had been drilled and charged. Connections were made to the firing line which was locked open on the surface and short-circuited. The firing-line switch on the surface was a double-pole type, and two wires were brought from it to the bottom of the shaft. The men prepared to go to the surface. They signaled the hoist operator and climbed into the bucket. The rope tightened, suspending the bucket; but it swung to one side of the shaft, came in contact with the firing wires, and exploded the charge.

The actual cause of this accident was never definitely determined. Investigators believed that a portion of the return current from the hoist motor traveled down the hoist rope and through the explosive charge into the earth. No fault was discovered in the hoist motor or its control equipment, however, and there is also a possibility that the flow of current was from the earth to the hoist rope through the explosive charge. Faulty track bonding or high-resistance grounded return circuits could be responsible for such an accident.

At an Alabama mine the face of a room had been drilled and charged. The shot-firing wires were short-circuited near the room neck. A water-pipe line was installed in the room, and bare spots in the firing line were in contact with it. A locomotive was switching cars in an adjoining room at the time that the miner connected his firing line to the lead wires, exploding the shot. In this instance it is thought that a portion of the electric current from the locomotive operating in the adjoining room flowed over the pipe line, causing a difference in potential between two bare spots in the firing line; the current was powerful enough to detonate the charge.

Another shot-firing accident in the same mine severed a miner's hand at the wrist. The miner had prepared the primer and was carrying it to the face. A mine car was in the place about eight feet from the face and as he passed alongside of the car, the ends of the detonator lead wires of the charge in his hand were dragging along the bottom when the charge went off. In this instance it was thought probable that one end of the wire had contacted the rail and that enough current flowed from the mine strata to the rail to cause the explosion.

Another accident, which fortunately did not result in an injury, occurred as follows: Explosive charges in two holes in the bottom bench had failed to fire and were covered by loose coal dislodged by shots in the upper bench. The coal was being loaded out on the next shift by a mechanical loader. One of the holes was detonated by stray currents and the operator jumped away from the machine, leaving it running. The operator's helper was standing on the pile of loose coal nearby. When the second shot went off, he was toppled over into the machine conveyor. These shots were unquestionably exploded by stray currents, the source of which probably was the mechanical loader. This would be possible only if the frame of the loader were grounded to the negative or a fault existed in the electrical system of the loader itself. Such accidents emphasize the importance of proper maintenance and effective grounding in operating mining machinery.

Paper 48-318, recommended by the AIEE mining and metal industry committee and approved by the AIEE technical program committee for presentation at the AIEE Southern District meeting, Birmingham, Ala., November 3-5, 1948. Manuscript submitted August 23, 1948; made available for printing October 11, 1948.

L. H. HARRISON is mining-electrical engineer, coal-mine inspection branch, Bureau of Mines, Birmingham, Ala.

Some Accidents from Stray Currents Due to Lightning Discharge

When a discharge of lightning occurs, the visible disturbance in the atmosphere is only part of the complete stroke mechanism. At the time of discharge, an electrical disturbance takes place within the orginating cloud formation. Moreover, a similar disturbance also is set up in the earth when discharges to the earth's surface occur. Electric currents of enormous intensity flow in the earth under discharge conditions. The earth offers resistance to the flow of current, and voltage gradients are built up in the earth's strata. Such voltage is enough to detonate explosive charges at a considerable distance from the point of entry into the earth.

Currents due to lightning, either direct strokes or from induced charges, are carried into the underground workings through mine tracks, pipe lines, or electrical feeder circuits and are dissipated in the earth. Differences of potential are thus created which have been known to cause the detonation of explosive charges several thousand feet from the mouth of a mine.

Short-circuiting of the detonator lead wires or shot-firing lines previous to the actual firing undoubtedly has prevented many premature detonations. This method, however, is not entirely effective in preventing such accidents. It is possible that heavy currents in the earth due to lightning discharges may cause a current to flow in the closed blasting circuit by the process of induction. Tests made at the Bureau of Mines' experimental mine, Bruceton, Pa., indicated that a voltage could be induced in an insulated wire buried in a shallow trench or lying on the surface. These experiments were made in connection with a ground conduction communication investigation. Voice-modulated currents at audio frequencies were fed into the mine strata by means of the mine track or grounding electrodes in the mine roof. They were picked up on a single insulated wire and on an insulated wire loop. The single wire was buried in a shallow trench about three inches below the surface. The loop was used with one side buried in the same trench and with the other side of the loop supported about two feet above the surface. The voice signals were picked up in this manner and amplified by means of a standard audio amplifier such as used in public address systems. The input current from the underground transmitter was in the order of a few milliamperes. The vertical distance through the earth strata from the point where the signals were fed into the earth was approximately 100 feet. Because of the minute currents involved in this experiment, it seems entirely possible that currents of sufficient intensity to detonate explosive charges could be induced in the closed loop of a shot-firing circuit under certain conditions of lightning discharge.

Abundant evidence has been accumulated to prove that lightning has caused the detonation of explosive charges in underground and open pit mines. Such instances have occurred under circumstances in which the secondary cause would appear to be electric currents flowing in the earth strata owing to lightning discharges from cloud formations to the earth's surface.

Two premature explosions in a limestone mine at Mullins, Ky., were attributed to lightning. In the first instance some six or eight holes had been loaded when the foreman in charge was notified that an electrical storm was in progress. He immediately stopped the loading of holes and came out of the mine with his crew. The wires from the several holes had not been connected but were left hanging loose. Shortly after the foreman and his crew reached the outside a keen clap of thunder was heard and lightning appeared to strike near the top of the hill under which the mine was located. Immediately thereafter, an explosion was heard in the mine. After the storm subsided an investigation was made, and it was found that the charges in six holes had been detonated.

In the second instance the circumstances were almost identical with the first instance, except that at the time the foreman was advised of an electrical storm occurring outside he had connected the wire and attached the lead line. As the foreman and his crew came out of the mine, he unreeled the lead line in such a manner that it was in contact with an exposed compressed-air pipe line. Shortly after the men had left the mine, there was considerable thunder accompanied by sheet lightning and all the loaded holes were discharged.

An article[1] written in 1933 gave a description of the premature firing of 16 of 36 holes in an underground limestone mine of the Washington Building Lime Company, Bakerstown, W. V. The article stated that the men had charged 36 holes and were some distance from the surface, the firing lines were not connected, and the cause of the premature blast was attributed to lightning.

The foregoing further emphasizes the fact that the utmost care must be exercised in the handling of electric blasting circuits, if premature blasting accidents are to be minimized. Firing lines should be well maintained and contact between the bare ends of lead wires and pipes, rails, or the mine strata itself should be avoided.

Stray Currents from Local Power Sources

The other main source of stray currents in coal mines, unlike lightning, presents a constant hazard. Stray currents from mine feeder systems and haulage tracks are ever present in the mine strata. They are carried to the working faces by track rails, pipe lines, wire ropes, grounding conductors, and so forth.

Perhaps the most prolific source of stray currents in coal mines is the haulage track. Electric trolley locomotives provide the most common type of haulage in mechanized coal mines, and the grounded track is the return power conductor for the locomotives and other equipment that receives power from the trolley circuit. The track ordinarily has ample carrying capacity to transmit the currents involved, and therefore it is usually considered wasteful and unnecessary to install feeder cables in the grounded portion of the circuits. The mine tracks inherently present a low resistance contact to earth, and thus the earth or mine strata becomes a coconductor with the mine track. Any difference of potential due to voltage drop in the track circuit also appears in the mine strata, and differences of potential can be measured between various points of contact in the mine floor, ribs, or roof. Such differences give rise to the flow of stray currents in the mine strata.

Some coal beds are laminated with bands of foreign material, such as clay or shale, that has a high moisture content and a fairly high degree of electrical conductivity. When locomotives or other electric apparatus operate in face regions, a portion of the current used by such equipment may flow through the bands of foreign material. This condition often is aggravated by poor bonding of tracks or the entire lack of bonding in face regions. Poor bonding or entire lack of bonding is one of the principal reasons for stray electric currents in the face regions of operating coal mines.

Water spray lines and frame-grounding conductors connecting the bonded mine track with the frames of mining machines and coal-loading equipment provide a low-resistance path for stray currents into the face of a room or wall. The

development plan of a mine often involves the installation of bonded tracks in parallel entries. When a room is driven from one entry, the face of the room may gradually approach an adjacent parallel entry. Two paths for the flow of current are thus set up, one in the first entry track and the other in the room track, pipe lines, grounding conductors, and so forth, to the face of the room, thence through a short section of the coal bed to the track in an adjacent parallel entry. The circuit of a d-c motor-driven machine may become faulted or grounded to the frame of the machine. If the fault occurs on the return side of the circuit the operation of the machine may not be affected. A poor return circuit for such a faulted machine may cause an appreciable amount of the machine current to flow in pipe lines or through the intervening strata or coal bed to tracks in an adjoining entry.

Another source of stray currents is leakage from an accidentally grounded conductor of a mine feeder system. Grounded power conductors frequently have caused mine fires owing to leakage of current heating and igniting the coal; this is conclusive evidence of the flow of current in the mine strata. In most instances the ground circuit presents a high impedance to the flow of current and may not be detected until after a long period of time. Simultaneous grounds may occur on opposite phases of a system at remote locations. Current will flow in the earth between such ground faults and may cause premature blasts under certain conditions.

On 3-phase Y-connected grounded neutral power systems, enough current may flow in the earth under fault conditions to cause premature detonation of explosive charges.

This may be true even where a grounding conductor is installed with the feeder system, unless provision is made for limiting the fault current by means of resistors or reactors in the grounding circuit.

Electrolytic action upon the metallic sheath or armor of power and telephone cables is another harmful result of stray electric currents. Frequently voltage readings from cable sheaths to ground will be found to vary directly with the load on d-c substations supplying mine loads. Such deleterious action, though not ordinarily hazardous to human life, results in damage to expensive cables and may result in costly outages.

Conclusion

The notoriously careless manner in which electrical installations are made in and around coal mines is an important factor in producing stray currents. The benefits to be derived by the reduction of such currents to a minimum are not always tangible. The Bureau of Mines for many years has recognized the dangers represented by haphazard and inadvertent methods of installing and maintaining electric equipment in coal mines. The Bureau has endeavored to bring about an improvement in the general quality of mine electrical installations by disseminating knowledge and by inspection and assistance. The Federal Mine Safety Code has been helpful in bringing about such improvement. Considerable progress has been made but much remains to be done. The day may not be too far distant when the electrical installations in a coal mine will compare favorably with those of any other industry having comparable problems. It can be done.

Report of the Board of Directors

THE BOARD OF DIRECTORS of the American Institute of Electrical Engineers presents herewith to the membership its 64th annual report, for the fiscal year ending April 30, 1948. It includes a general balance sheet and other statements showing the financial condition of the Institute at the close of the fiscal year and a brief summary of the principal activities of the Institute during the year, more detailed information having been published from month to month in *ELECTRICAL ENGINEERING*.

BOARD OF DIRECTORS' MEETINGS

Five meetings of the board of directors were held during the year, two in New York, N. Y., one in Montreal, Quebec, Canada, one in Chicago, Ill., and one in Pittsburgh, Pa.

Information regarding many of the more important activities of the Institute which have been under consideration by the board of directors and AIEE committees is published each month in the section of *ELECTRICAL ENGINEERING* devoted to Institute activities.

ANNUAL MEETING

The annual business meeting of the Institute was held on June 11, 1947, in Montreal, Quebec, Canada. The annual report of the board of directors for the fiscal year which ended April 30, 1947, was presented in abstract by Secretary H. H. Henline, and the Institute's financial situation was reviewed by Treasurer W. I. Slichter. The report of the committee of tellers on the election of officers for the year which began on August 1, 1947, was presented, and President-Elect Blake D. Hull responded to his introduction with a brief address. National prizes for papers were presented.

The Lamme Medal for 1946 was presented to John B. MacNeill, manager of the switchgear and control division, Westinghouse Electric Corporation. The president's address by J. Elmer Housley concluded the meeting.

GENERAL MEETINGS

A brief report on each of the four general meetings held during the year follows:

Summer General Meeting. The 63d summer general meeting was held in Montreal, Quebec, Canada, June 9–13, 1947, with a registration of 1,451. The program included 13 regular technical sessions, 14 conference sessions, 10 administrative conferences, and about 25 committee meetings, in addition to the afore-mentioned annual business meeting. There were entertainment events, inspection trips, golf tournaments, a president's reception, a banquet, and a dance.

Pacific General Meeting. The Pacific general meeting was held in San Diego, Calif., August 26–29, 1947, with a registration of 589, a new attendance record for the meeting. There were 15 sessions, including two devoted to the presentation of student papers, a luncheon with address by President Hull, Student Branch conference and a conference of District and Section officers, inspection trips, a golf tournament, and numerous social and entertainment activities including a "Night in Old Mexico," with dinner at Serena's in Tijuana.

Midwest General Meeting. The first Midwest general meeting was held in Chicago, Ill., November 3–7, 1947, with a registration of 1,449. This meeting is to be held annually in the "Middle West." The Chicago meeting included three general sessions, seven technical sessions, and nine technical conference sessions, including one held jointly with the National Electronics Conference. About 40 meetings of general and technical committees were held. The program included a dinner-smoker with entertainment, many inspection trips, and numerous events for the women.

Winter General Meeting. The winter general meeting was held in Pittsburgh, Pa., January 26–30, 1948. The registration was 3,081. A total of 51 technical sessions included 18 for formally approved papers, 18 for informal conference papers, and 15 at which both types of papers were presented. Meetings were held by about 75 technical and general committees. The Edison Medal for 1947 was presented to Doctor Joseph Slepian. Other features were a smoker, a dinner-dance, many inspection trips, and a generous program of social and entertainment events for the women.

DISTRICT MEETINGS

Middle Eastern District Meeting. The first Middle Eastern District meeting since 1940 was held in Dayton, Ohio, September 23–25, 1947. The registration was 502. There were eight technical sessions and one general session. Papers presented included 28 formally approved and 12 conference papers. The program also included a banquet, inspection trips, and special features for the women. The District executive committee held an all-day meeting on September 22.

Great Lakes District Meeting. The eighth Great Lakes District meeting was held in Des Moines, Iowa, April 1–3, 1948, with a registration of 357. Seven technical sessions provided for the presentation of 13 formal papers, 8 conference papers, and 10 undergraduate and 7 graduate student papers. President Hull gave the principal address in the opening session on the subject "Ceiling Unlimited." There were several inspection trips, a banquet, a general luncheon, and numerous events for the women.

North Eastern District Meeting. This meeting was held in New Haven, Conn., April 28–30, 1948, with a registration of 669. The technical program included 17 formally approved papers, 27 District papers, and 11 student papers. There was a general session with four addresses. Other events were a District executive committee luncheon, a dinner, inspection trip, and various events for the women.

TECHNICAL CONFERENCES

A conference on electron tubes held in Philadelphia, Pa., March 29–30, 1948, and a conference on electrical problems in the rubber and plastics industries held in Akron, Ohio, April 20, 1948, introduced a new activity devoted to more extensive consideration of specialized technical subjects. The first was sponsored by the joint subcommittee on electron instruments of the committees on electronics and instruments and measurements, with the co-operation of the Philadelphia Section. The second was sponsored by the subcommittee on rubber and plastics of the committee on general industry applications and the Akron Section.

General Committees

FINANCE COMMITTEE

As seemed inevitable from recent trends, the fiscal year ending on April 30, 1948, showed a substantial operating deficit.

While we had a $75,500 (almost 14 per cent) increase in income, our expenditures increased $144,000 (or 27 per cent), resulting in a deficit of approximately $44,500. This deficit was met by withdrawal from our reserve capital funds.

For the budget year October 1, 1947, through September 30, 1948, the board of directors adopted a budget which, in spite of efforts to hold appropriations to a minimum consistent with the vigorous and progressive activities of the Institute, showed a deficit of some $23,000. This was after taking full account of the anticipated growth in membership and the substantial increase in advertising revenues expected to result from higher advertising rates and more active advertising sales effort. Subsequent experience has indicated that costs will be even higher than budgeted without corresponding increases in revenue, so that the budget year deficit is expected to somewhat exceed the original budget estimate but should not be in excess of the $44,500 operating loss for the fiscal year just ended.

Because these trends raise the obvious question as to whether continually increasing costs per member can be met without increasing payments per member, President Hull appointed a special committee to study the whole matter and recommend a course of action. Fortunately, we have a capital reserve fund that is adequate to tide us over any deficits that can be anticipated for the immediate future unless there should be a sharp recession with resultant drop in revenues from membership dues and advertising.

COMMITTEE ON PLANNING AND CO-ORDINATION

Further work has been done toward implementing the Institute's technical activities as reorganized last year and as outlined in the memorandum by Doctor Wickenden.

The four co-ordinating committees of the technical committees each have served, as the name implies, to harmonize and advance the activities of their respective technical committees. Committee scopes, membership lists, and agenda have been correlated and new work initiated. The co-ordinating committees warranted more formal status by defining certain general items of their scopes and this has been done by the committee.

A technical activities subcommittee was continued, the membership this administrative year consisting of the chairmen of the four co-ordinating committees. The purpose of this subcommittee was to correlate the activities of the co-ordinating committees, to keep the committee on planning and co-ordination informed as to progress being made in the co-ordination of the various technical activities of the Institute, and to serve as a medium of co-ordination on a national and on a Sections basis. This technical activities subcommittee has aided in eliminating duplication of technical effort by the Institute's technical committees with those of other organizations. It is clearly evident that the co-ordinating committee setup is working out admirably well. The committee recently has decided to augment the personnel of the technical activities subcommittee to include the vice-chairmen, as well as the chairmen, of the four co-ordinating committees, and also the chairman and vice-chairman each of the technical program and Standards committees.

There have been two groups in the Institute's organizational setup, one known as the administrative group and one as the professional group. The administrative group is not now serving any particular need, and the committee has recommended and the board of directors approved the discontinuance of this group at the end of the present administrative year.

The new scopes of the power group committees were endorsed and recommended to the board of directors for approval. Changes in names of certain committees in the industrial and power groups were considered and approved. The formulation of a new committee on computing devices also was approved together with suitable scope. The scope for the new committee on management was reaffirmed.

The committee has considered the invitations received and recommended to the board of directors specific locations and dates for future national and District meetings for the next three years. It is necessary that these be determined well in advance of the scheduled dates so that suitable arrangements can be made.

A new type of meeting recently has been conceived known as the "technical committee conference." This may be defined as a program of panel discussions, technical papers, or exhibits under the auspices of a national technical committee, or subcommittee. The purpose of these meetings is to expand technical committee activities on individual specialized subjects and to serve the interests of members and nonmembers on that subject. Two of these technical conferences have been held to date: one on the subject of electron tubes at Philadelphia during March and one on rubber and plastics in Akron during April. It has been reported that these conferences were extremely successful and the committee believes every encouragement should be given them.

A recommended policy for these technical committee conferences was established. This includes definition, scope, financial arrangement, and authorization for such conferences. The authorization is to be in the hands of the chairman of the co-ordinating committee affected and he will correlate with the technical program committee and others. The board of directors will need to be consulted only when financing is involved.

The subject of Institute prize awards is being restudied in detail. A subcommittee of the Sections committee has undertaken this work and a report with recommendations is expected later this year.

Work has been initiated covering the establishment of a publicity policy for the Institute. A statement of policy prepared by the committee on publicity has been approved by the committee on planning and co-ordination and by the board of directors.

There has been considerable discussion regarding the need for and the procedure to be followed in "Organization of the Engineering Profession." The committee has recommended and the board of directors has approved the following resolution:

RESOLVED:

1. That the resolution adopted by the board of directors at its meeting on November 5, 1947, be reaffirmed and that the board express its desire for prompt action.

2. That the board (of directors) ask its representatives of the EJC (Engineers Joint Council) to request very prompt action be taken on this matter.

3. That the board (of directors) authorize President Hull, and representatives designated by him, to accept invitations from the boards (of directors) of other national engineering societies to present the views of the AIEE.

Numerous proposed modifications of the Institute's constitution and bylaws have been reviewed and discussed. Certain changes have been approved for submission to the board of directors.

The Italy America Society, Inc., has offered the Institute certain funds, and suitable plans are to be developed for the administration of such funds if they become available.

PUBLICATION COMMITTEE

The new publication policy, which went into effect January 1, 1947, now has been in effect for 16 months, and in general is functioning successfully and satisfactorily according to plan. The full details of the new program were explained to the membership by the then chairman, C. F. Wagner, of the publication committee, in an article (*EE, Dec '46, pp 576–8*); and the essential substance of these same details was embraced in the 1947 report of the publication committee to the board of directors. A few necessary modifications and minor adjustments of details have been made according to the requirements of the circumstances as the new procedures have been developed and applied.

The plan provided for three basic correlated publications, *ELECTRICAL ENGINEERING*, *TRANSACTIONS*, and *PROCEEDINGS*. This program seems to be meeting very well the broad and diverse interests of the membership, according to questionnaires which were circulated at the 1947 summer general meeting and at the 1947 Pacific general meeting, and also as indicated by informal comments and discussions at other meetings and by correspondence received from individual members.

In summary, the highlights of the publication year are: the improvement in the physical appearance of *ELECTRICAL ENGINEERING*, the increase in the advertising content, and the improved scope and subject balance of the text material published; the adoption of a flat price for the advance pamphlet copies of technical program papers, regardless of the number of pages of the pamphlet, in place of the previous and more complicated sliding-scale price schedule; the successful initiation of the new interim publication service to the Institute members represented by the newly re-established *PROCEEDINGS*, and the related and surprising discovery that the actual membership demand for *PROCEEDINGS* is materially lower than initially was contemplated; the postponement of publication of the 1948 "Year Book" for the purpose of establishing a new and more effective publication cycle co-ordinated with the administrative year, which begins the first of August.

ELECTRICAL ENGINEERING. *ELECTRICAL ENGINEERING* continues as the general service publication which reaches all members, all Student members, and a substantial list of nonmember subscribers. With the release of previous space commitments for *TRANSACTIONS* pages in *ELECTRICAL ENGINEERING*, the scope and nature of subject matter published in the monthly has been, and still is being, progres-

Table I. Numbers of Pages of Published Material

	ELECTRICAL ENGINEERING			*TRANSACTIONS* Only		
Year	General Interest Articles	News	Transactions Section	Technical Papers	Discussions	Totals
1941	337	281	600	542	268	2,028
1944	246	214	738	493	231	1,922
1945	255	225	736	121	143	1,480
1946	285	315	832	254	120	1,806
1947	806	474	1,463*	153*	2,896*	

* Preprinted in 227 sections of AIEE *PROCEEDINGS*, except for a 17-page technical paper in *ELECTRICAL ENGINEERING*.

sively broadened to serve better the diversified interests of the membership and to supplement the complete formal technical papers published in *PROCEEDINGS* and *TRANSACTIONS*. Direct contact with these formal papers has been maintained for all readers of *ELECTRICAL ENGINEERING*, however, by virtue of the fact that either the full text or essential substance of a large number of technical papers has been published in *ELECTRICAL ENGINEERING* and at least a brief abstract of all the other *TRANSACTIONS* papers has been published. A significant change and further improvement in this service has been made and is taking effect as this report is issued in June, in that the previous very short abstract, often merely descriptive of the paper rather than revealing its subject matter, has been developed into a digest article, each of which with one or two illustrations will comprise units of approximately one page in *ELECTRICAL ENGINEERING*. Thus, every reader is assured of receiving at least the essential substance of every technical program paper.

The physical appearance of *ELECTRICAL ENGINEERING* was improved beginning with the September 1947 issue by a change to white paper of better quality, and a further change was made in the finish of the new paper to improve the quality of printing, effective with the April 1948 issue. In general, the paper supply situation has eased to a point where, with the close co-operation of suppliers, it has been possible to meet the steadily growing requirements for *ELECTRICAL ENGINEERING* paper. Severe production delays and other related difficulties incidental to protracted printing congestion have continued, with resulting tardiness in the issuance of the monthly edition. This has been annoying to readers and to advertisers, and has compounded the production difficulties of the editorial staff. As this report is issued, however, substantial improvement is being made at long last in the printing schedule, and it seems reasonable to hope that *ELECTRICAL ENGINEERING*'s mailing schedule of the 22d of the month preceding the date of issue can be re-established with the May 1948 issue.

ELECTRICAL ENGINEERING's circulation of the April 1948 issue was 45,000, one of the highest in the whole field of technical and professional journals. The steady growth of this circulation during recent years is indicated in the following:

January 1948	43,000
January 1947	36,300
January 1946	29,000
January 1945	26,450
January 1944	25,000
January 1943	24,900
January 1942	24,800
January 1941	23,900
January 1940	23,000
January 1935	18,500

The number of pages of published material for a few years back is shown in Table I, and there is a very large increase in 1947. This increase is a reflection, to a degree, of the additional number of general meetings, and of the effort to supply the readers' demands.

Advertising. Advertising policies and procedures have been given special attention by the publication committee and by the board of directors during the year. A more active advertising program was adopted, a new advertising director joined the publication staff at headquarters, advertising field representatives located in Chicago were engaged to service the Middle West territory, and advertising space rates approximately were doubled to bring them to a level more nearly commensurate with *ELECTRICAL ENGINEERING*'s production costs and high level of circulation. Also, advertising agency commissions were established, in accordance with prevailing trade practice. The resultant effect of these changes, while not fully felt to date, was to arrest the definite and alarming downward trend in advertising revenue, and actually did produce an increase in 1947–48 over 1946–47. Further effect is expected in 1948–49.

An interesting and useful 4-page pamphlet was prepared, entitled, "Industry Depends on the Electrical Engineer," which shows the geographical paid distribution and occupational analysis of readers for 1947 for 40,847 circulation of *ELECTRICAL ENGINEERING*. These data will be of great use and help in our advertising campaign.

PROCEEDINGS. Under the new publication program, the *PROCEEDINGS* was established expressly for the purpose of providing a special interim service for those members especially interested in the early availability of the full and complete technical and mathematical details of subject matter within the fields of their particular professional interests, including the discussions of the papers presented. In effect, the *PROCEEDINGS* is a preprint service from the annual *TRANSACTIONS* through which members may receive *TRANSACTIONS* papers and discussions many months ahead of their best possible availability in the *TRANSACTIONS* volumes. The *PROCEEDINGS* sections are made available to the membership through the medium of order forms which are published from time to time in *ELECTRICAL ENGINEERING* as the material covered is about to become available for distribution. The 1947 *TRANSACTIONS* papers were serviced by order forms published in the February, June, and December 1947 issues of *ELECTRICAL ENGINEERING*, and the first year's experience indicates that about 2,000 members are availing themselves of this *PROCEEDINGS* service. In brief, the governing policy is that single copies of *PROCEEDINGS* sections may be obtained by any member through the use of the order form, up to ten per cent of the items on any order form free and additional items at a flat subsidized price of ten cents each if remittance accompanies the order; Student members may procure desired *PROCEEDINGS* sections at ten cents each through the use of the order form. So far as it has been possible to determine, this is a pioneer effort in such selective distribution of diversified publications. It is working out quite closely in accordance with expectations, except that the quantity requirements are substantially lower than were contemplated. Except for the production and distribution delays resulting from printing congestion, which have been quite severe, the membership reaction to this specialized service has been strongly favorable.

As the first year of this service came to a close, the printing-production delays were being substantially overcome, with the result that a corresponding reduction has been possible in the time delay between receipt of a member's order form and the mailing of the requested *PROCEEDINGS*. However, there is a minimum delay below which it is impossible to go. This minimum delay is dictated by two factors: first, the fact that the final processing of a technical paper manuscript cannot even be started until about a month after the date of a meeting at which the paper is presented, when the meeting discussion on that paper becomes available; second, the fact that in the interests of production economy it is necessary to equalize over a 12-month period the peak load influxes of new material related to the various District and general meetings.

In accordance with the action taken by the board of directors at its November 1947 meeting, the general governing policy has been established that the primary objective of the *PROCEEDINGS* is the immediate distribution of requested technical material in minimum possible time after publication of an order form in *ELECTRICAL ENGINEERING;* that such order forms will be honored subsequently within the limits of available printed stock of *PROCEEDINGS*, that no effort will be made to maintain stocks of *PROCEEDINGS* available for distribution after the issuance of the *TRANSACTIONS* volume containing the material from those *PROCEEDINGS*.

Preprints. The practice of issuing technical program papers in pamphlet form (preprints) in advance of the meetings for which they are scheduled is being continued in line with the general publication policy. Some changes in procedural details have been made, however, in line with the recommendations of the finance committee as embraced in the budget action of the board of directors at its November 1947 meeting: first, free distribution is limited to a maximum of five copies of a paper to go to each author, and not to exceed ten copies of each paper to be available to the sponsoring technical committee expressly for the purpose of inviting and stimulating specific discussions; second, the establishment of a flat member price of 30 cents per copy (nonmembers 60 cents) regardless of the number of pages and

regardless of whether procured by mail or personally at headquarters or meetings; third, the provision that authors or the companies with which they are affiliated may procure, by written order submitted with the final draft of the manuscript, nominal quantities at the individual member price of 30 cents per copy in advance of the meetings, leaving large quantity orders to be serviced and quoted upon separately by headquarters after the initial requirements for the meeting have been satisfied. This latter restriction was essential to reduce and avoid critical premeeting congestion in the printing and distribution of this material.

Special Publications. Several special publications were produced during the year and made available for sale in accordance with announcements carried in *ELECTRICAL ENGINEERING*. These include:

1. "Application of Electric Conversion Equipment to the Electrochemical Industry"
2. "Bibliography on High-Frequency Dielectric Heating"
3. "Electric Power Applications in the Textile Industry"
4. "Electric Power in the Pulp and Paper Industry"
5. "Statistical Methods in Quality Control"
6. "Tidd 500-Kv Test Lines"
7. "Report on Electron Tube Survey of Instrument Manufacturers and Laboratories"

Year Book. Effective with the 1948 edition, the "Year Book" will be published and distributed in the early fall, probably during September, instead of early in the spring as it has been in recent years. The objective of this change is to make available at the beginning of the AIEE administrative year, an up-to-date roster that will be of maximum service to the new officer and committee personnel and other members. This change was recommended by the publication committee on the basis of a questionnaire survey, and approved by the board of directors at its January 1948 meeting.

The 1948 "Year Book" also will include the 1947–48 officers, so that there will be no break in the publishing of these lists.

Administrative. In addition to the very heavy production load picked up by the editorial staff incidental to the activation of the enlarged publication program in 1947, there was the attendant difficulty of procuring and retaining the necessary qualified personnel. Typical of prevailing economic and industrial conditions, the turnover in editorial personnel for the year was exceedingly high, the equivalent of 100 per cent staff turnover in terms of the number of persons involved, and the losses in training and production time. This condition seriously impeded operations and materially reduced production efficiency. However, toward the close of the fiscal year covered by this report, appreciable improvement had been accomplished and the situation seemed to be approaching a degree of reasonable stability in terms of qualified personnel, and the substantial assistance of the finance committee and the board of directors toward the accomplishment of this condition hereby is appreciated and acknowledged.

Costs. The cost of publishing *ELECTRICAL ENGINEERING* and associated printed matter materially has increased. This is due to a number of factors, among which are

1. Paper cost.
2. Printing cost.
3. Additional pages in *ELECTRICAL ENGINEERING*, additional preprints, and additional *PROCEEDINGS* as a result of a third general meeting.
4. Editorial staff payroll increases.
5. Increased circulation.

Of course, there are a number of revenue increases to compensate to some extent for these cost increases, and among these are increased advertising rates, increased charges for preprints, and so forth.

SECTIONS COMMITTEE

1. Section Activities. Section activities have continued at accelerated postwar levels, as indicated in the following:

New Sections organized

Arkansas
Arrowhead, Minn.
Canton, Ohio
Panhandle Plains, Tex.
Rock River Valley, Ill.
Shreveport, La.

New Subsections organized

Binghamton Area, N. Y.
Corpus Christi, Tex.
Fox River Valley, Wis.
Freeport, Tex.
Johnstown, Pa.
Little Falls, Minn.
Quad Cities, Iowa
Red River Valley, Minn.
St. Maurice Valley, Quebec, Canada
San Jose, Calif.
San Juan, Puerto Rico
Shasta, Calif.
West Central Texas
Western Virginia

The Sections committee actively has encouraged aggressive Section programs and has cosponsored Section membership promotion meetings.

The booklet "Section Activities," prepared by last year's Sections committee, has been circulated to Section officers and all other interested Institute officers and committeemen. This excellent work covers all essential Section activities.

During the current season, an outline of model Section activities has been perfected under the direction of Fischer Black, Sections committee member from the Washington Section. This will assist materially new Section officers as a guide and check sheet for each item of successful Section operations. This outline will be presented in its final form at the Sections committee meeting in Mexico City.

2. Bylaws Changes. Several amendments to the Institute bylaws have been recommended by this year's Sections committee. One of these formalizes the recognition of Subsections and Section Divisions; another, increases from 25 to 50 the number of members required on a petition for Section status. This recommendation is based on the fact that practically all Sections authorized within recent years have developed from Subsections or Section Divisions and the fact that it is not economically sound to have Sections of the Institute with less than 50 members.

Another recommendation for a change in bylaws proposes that any Section having less than 30 members or holding less than four meetings during a fiscal year will be changed to a Subsection at the end of the following year if during the interim period sufficient activity has not been exhibited to conform with the foregoing requirements.

3. Subcommittees on Prize Paper Rules and Section Finances. A subcommittee of the Sections committee, under the chairmanship of Fischer Black, has been appointed to study and make recommendations for changes in the Institute prize paper rules. This subcommittee is expected to report at the meeting of the Sections committee in Mexico City.

Another subcommittee of the Sections committee, under the chairmanship of Victor Siegfried of the Worcester Section, has been appointed to study the subject of "Section Finances." This committee likewise will report at the Mexico City meeting.

4. Section Committee Meetings. The Sections committee held a meeting in Pittsburgh on January 28, 1948, with 55 members and guests in attendance. Actions at this meeting included recommendations to the board of directors for the assignment of Alaska to the Seattle Section and District number 9, in addition to the recommended changes in bylaws and other actions mentioned in other parts of this report.

The Sections committee will conduct a conference on Section operation and management, and a delegates' get-together during the summer general meeting in Mexico City.

5. Co-operation With Other Institute Committees. The Sections committee has maintained active co-operation with the Institute committees on membership transfers, Student Branches, and technical program, the industry co-ordinating committee, the general industry applications committee, the industrial power system subcommittee, and to a lesser degree many other working committees of the Institute.

COMMITTEE ON RESEARCH

The principal activity of the committee during the past year was the sponsoring of a symposium on new materials at the winter

Table II. Section and Branch Statistics

	For Fiscal Year Ending April 30					
	1943	1944	1945	1946	1947	1948
Sections						
Number of Sections	73	73	73	75	75	81
Number of meetings held	598	738	884	1,210	1,333	1,340
Total attendance	66,111	83,120	96,346	113,531	155,649	109,637
Branches						
Number of Branches	125	125	125	125	126	127
Number of meetings held	942	755	547	716	1,018	1,172
Total attendance	38,227	24,768	17,132	22,844	40,669	77,040

general meeting. A total of 14 papers was presented, principally in the fields of magnetic materials, dielectrics, insulations, and semiconductors.

The papers brought out a considerable amount of new information which may influence future trends in electrical engineering practice to a significant degree.

A summary of the properties of the materials discussed also was prepared for the proceedings to make the significant parts of the information readily available.

Proposed papers for the summer general meeting were reviewed.

A former activity of this committee, namely, the listing of suggested research projects for which it is deemed there is considerable need is again under consideration by the committee as a possible future activity.

STANDARDS COMMITTEE

During the early months of the year 1947–48, the Standards committee approved a large number of Standards and codes, some of which had been in course of development for long periods, because of wartime activity demands on the time of many of those making up the originating committees. Since the June 1947 meeting, a large part of the committee's time has been devoted to the reorganization and reactivation of committees whose personnel had been affected by changes in member business affiliations following the war.

One of the projects on which formal approval was obtained, was the report of the special committee on sign of reactive power under R. C. Bergvall, as chairman. For years this question has been the subject of controversy among the various interested groups. After a careful study of all the factors involved, a utilization of all available publicity in obtaining criticisms and suggestions, formal action reversing the present AIEE Standards was taken, that is, a change of the sign of reactive power from minus to plus.

The subcommittee on applications of statistical methods to quality control, under Chairman Dobson, having arranged for the presentation and publication of 11 papers on that subject, now is negotiating with the American Society for Quality Control, for the obtaining of additional papers on application in the electrical field as well as the institution of an educational campaign toward the wider application of quality control.

The prospect for future Standards activities seems to have been enhanced by the recent enlargement of the Institute technical committee structure. The greatly increased number of technical committees certainly should result in greater interest and activity in each individual field. A resumption of activity in the International Standards field also can be expected, due to the recent organization of the International Organization for Standardization. The United States National Committee of the IEC, while inactive during the war, again will take over the handling of the American phase of the ISO work. With relation to this international phase of Standards work, attention is called to the successful international session held under the auspices of the Standards committee in Montreal on June 10, 1947, and the proposed session in Mexico City during the summer general meeting.

The work on aeronautical electrical Standards is going ahead with the active cooperation of the technical committee on air transportation under S. D. Summers, chairman. Direct contact now has been made with the chairman of the National Aeronautical Standards Committee, which it is hoped will lead to a closer contact than has been had in the past with those interested in the furtherance of such standardization.

During the past year the following Standards and codes have been approved by the Standards committee: General Principles Upon Which Temperature Limits Are Based in the Rating of Electric Machines and Apparatus (a revision); Electric Recording Instruments; Neutral Grounding Devices (a revision); Aircraft D-C Apparatus Voltage Ratings; Master Test Code for Resistance Measurements (a report); Letter Symbols for Physics; Potheads; Roof, Floor and Wall Bushings; Graphical Symbols and Abbreviations for Use on Drawings; Graphical Symbols for Electron Devices.

The sectional committee on definitions of electrical terms, for which the Institute is sponsor, a major AIEE project, inactive during the war, now has been reorganized completely under the chairmanship of Professor Dawes. The work of its 18 subcommittees is now well under way.

In a move to expedite both the approval of Standards and codes, and the appointment of AIEE representatives on various standardizing committees, Chairman Jones made an appeal to the board of directors for the delegation to the Standards committee of the power to give such approval in the name of the Institute. The board of directors approved his request on April 23, 1948.

TECHNICAL PROGRAM COMMITTEE

Technical Programs. The technical programs for the general meetings and District meetings have been kept on a high standard and at the same time enlarged to correspond to the growth in Institute membership. In Table III, the number of papers presented at each of the seven meetings which were held during the year are given, together with the attendance. The total of 233 *TRANSACTIONS* papers and 30 advance copy papers approaches closely the 270 average estimated number of papers a year for the five year period following 1945 presented in the 62d annual report of the board of directors for the fiscal year ending April 30, 1946.

Planning for Programs. In the arrangement of programs, an attempt has been made to cover all new developments in the field of electrical engineering and the allied arts. The geographical location of meetings also has been taken into consideration, and papers have been presented which were of particular interest in certain regions. For the summer general meeting in Montreal, sessions were held on power supply in paper mills and hydroelectric power generation. For the Pacific general meeting in San Diego, an important symposium on sonar was held as well as two sessions on aircraft. For the Middle Eastern District meeting in Dayton, the home of Wright Field and the heart of small motor manufacture, it was only natural that the program was devoted to electrical applications to aircraft and the design and performance of small motors. For the winter general meeting in Pittsburgh, a number of sessions were held which dealt with electrical applications to the production of iron and steel as well as mining.

Analysis of Subject Matter. In the field of power, two important symposiums on the Tidd 500-kv test lines were presented at the Midwest general meeting. The papers described the apparatus, line conductors, insulators, and hardware design for these test lines, and the resulting data will be of value in designing higher voltage transmission lines. In the field of communication, sessions on frequency and pulse modulation, sonar, and synthetic crystals were outstanding. In the industrial field, sessions on applications to the steel industry and the related control problems were significant contributions. In the field of general applications, the subjects of light traction, heavy traction, and the economics of power supply, as well as developments in Diesel electric locomotives have been well covered.

In Table IV, the papers have been classified on the basis of the technical committee structure in the Institute. Papers jointly sponsored have been indicated by half credits respectively. This is only one of several possible bases for the classification of papers. For example, if all of the papers which dealt with electronic applications, such as in the fields of electronic power converters, industrial control, electric heating, communication, and instruments and measurements were classified under electronics, there would be a great many more electronics papers. A number of valuable papers filling a definite need have been brought forth in the fields of electronic instruments, servomechanisms, and the heat pump. There also has been an increase in the number of communication papers presented during the year.

Midwest General Meeting. The meeting held in Chicago, November 3–7, inaugurated the first of the Midwest general meetings designed to fill a need in that section of the

Table III. Number of Papers Presented During the Year Ending April 30, 1948*

Meeting	District	Advance Copy Only	Conference Papers	Transactions	Total	Attendance

country and relieve the congested winter general meetings. Sixteen technical sessions and conferences were held, one of which was joint with the National Electronics Conference, and three general sessions. The meeting was very successful with a total registration of 1,449, and for the future indications are that the programs for this meeting will be larger. For the 1948 Midwest general meeting to be held in Milwaukee, 35 technical sessions and conferences already have been scheduled.

Future Meetings. The program for the summer general meeting in Mexico City has been completed, and the programs for the Pacific general meeting and the Midwest general meeting are well under way. Several sessions already are in prospect for the 1949 winter general meeting in New York.

Administration Group Committees

BOARD OF EXAMINERS

Statistics relating to the number of cases handled by the board of examiners during the year 1947–48 are given in Table V. The current total represents a slight increase in the record figures for 1946–47, or about 72 per cent more than the 1945–46 total. These figures are exclusive of those covering "Enrolled Students" which rose from 3,931 to 5,894, or about 50 per cent.

In the past the examiners frequently have emphasized the need for a more careful preparation of all applications, both for admission and transfer. The results of these pleas are evident in a considerable decrease in the number of transfers held up by the need for additional information. The examiners wish therefore to express their appreciation for the excellent work carried on by the Section transfer committees aiding in this connection. With regard to applications for direct admission, the examiners still find it necessary to ask frequently for more detailed statements of record and additional supporting references. A bare statement of titles of positions held with dates is not sufficient to enable the board of examiners to arrive at a decision on eligibility. Likewise, the fact that an applicant has reached the lower age limit specified in the constitution is no proof of eligibility.

Among the hundreds of cases that have been passed upon by the board of examiners, particularly since the end of the war, there have been many from foreign countries. This number seems to be growing at an unusually rapid rate. The examiners therefore have expressed the opinion that this situation should be called to the board of directors' attention. As the dues paid by such members are determined through adjustments based on currency exchange rates, resulting in payments in many cases 40 per cent below the stated dues paid by engineers in the United States, it would seem that in accepting foreign applicants under such conditions we may be aiding in making more acute a recognized existing shortage of funds for fulfilling our obligations to the membership in the United States.

COMMITTEE ON CONSTITUTION AND BYLAWS

Submitted by the committee on October 10, 1947, and adopted by the board of directors on November 5, 1947, were the following recommendations.

1. **Constitution.** In sections 39, 40, 50, 59, changing the word "convention" to "general meeting."

2. **Bylaws.** In sections 6, 7, and 11, changing the words "United States or Canada" to "United States, Canada, or Mexico."

Section 39. For the word "national," substituting the word "international."

Section 65. Adding to the list of general committees the "committee on management."

Section 85. For the word "national," substituting the word "general."

Section 85. Deleting last paragraph to remove repetition.

3. **New Section.** Outlining the membership and the cope of the new committee on management.

Submitted by the committee on January 7, 1948, and adopted by the board of directors on January 29, 1948, were the following recommendations.

1. **Constitution.** In section 10 requiring proposals for transfer to grade of Fellow to originate from "five Fellows," rather than from "five Members or Fellows." Section 20. Deleting entire section, to do away with "Life Membership."

Section 32. Changing the mailing date of election ballots from "the first week in April" to "April 15."

Section 35. Redefining the membership of the board of directors to read: "The board of directors shall consist of the president, the two surviving past presidents most recently retired, the vice-presidents, the directors, and the treasurer."

Section 44. Changing the requirement that "each standing committee shall include at least one member of the board of directors" to requiring that "each co-ordinating committee shall include at least one member of the board of directors."

Also, transferring this clause to section 65 of the bylaws.

2. **Bylaws.** In sections 6, 7, 22, and 63, deleting the words ("Journal of A.I.E.E.").

Section 21. Deleting the heading "Life Membership" and the table in section 22, headed "Life Membership Rates." Also, rewording section 21 to take care of present "Life Members."

Section 23. Changing the mailing date of election ballots from "the first week in April" to "April 15."

Section 33. Making optional the appointment of a District co-ordinating committee, and specifying that if appointed, such a committee "shall function continuously in an executive capacity for the District executive committee."

Section 35. Providing that a District meeting committee shall be "composed of members within the District, preferably located in the area where the meeting is to be held."

Section 35. Deleting the word "national" before the words "technical program committee."

Section 35. Changing the world "national" to "general."

Section 65. Under the heading "General Committees," adding the committees on education, management, Members-for-Life fund, Institute publicity, and transfers.

Section 65. Under the heading "Technical Committees," adding the new "committee on computing devices," and rearranging all the technical committees under their proper co-ordinating committees.

Table V. Application for Admission and Transfer, 1947–1948

Section 68. Adding to the technical program committee the chairmen of the technical co-ordinating committees, and the chairman of each of the following committees: education and research.

3. **New Section.** Defining the scope of the transfers committee.

Section 70. Adding to the planning and co-ordination committee the chairman of each co-ordinating committee.

Section 97. Clarifying the procedure relative to revisions of technical papers, before publication by the Institute.

The following recommendations of the committee were adopted by the board of directors on April 23.

1. **Bylaws.** Section 22. Defining the "suggestion to be considered by the nominating committee" to be those "from the general membership."

Section 32. Adding to the District executive committee a member of the Sections committee who is resident in the District.

Section 36. Changing the minimum number of members, who may petition for the formation of a Section from 25 to 50.

HEADQUARTERS COMMITTEE

As requested by the board of directors, the committee considered a proposal that the main lobby of the Engineering Societies Building be converted into a common board room, a suggestion which had been under consideration by the other founder societies and the United Engineering Trustees, Inc. The committee recommended that the proposal be not endorsed, as the amount of use of the AIEE board room precludes its discontinuance, the modification of the lobby was considered to be fundamentally undesirable, and the cost would not be justified by the benefits that would be derived.

The committee has kept in mind continuously the need for more office space in the building, and discussed various possibilities.

COMMITTEE ON INSTITUTE PUBLICITY

The committee on Institute publicity had as its primary task the handling of public relations for the winter general meeting held this year in Pittsburgh during the latter part of January. It was decided again to retain the services of a professional public relations counsel. Public Relations Research Service, Inc., of Pittsburgh was authorized to carry on this work, and it is believed that the assignment was completed in an effective manner.

Publicity for the summer general meeting in Mexico City is being handled by the local organization with assistance and suggestions from the general committee. Material on the over-all objectives and activities of the Institute has been sent to Mexico City, and the committee will continue to provide any other assistance that is required.

At the request of President Hull, the committee has formulated and submitted to the board of directors a draft of a statement of Institute publicity policy. The committee's suggestions recommend consideration of publicity as a continuing and integrated activity rather than a series of special efforts centered about a few important meetings.

At the same time, the committee submitted a tentative definition of its scope for inclusion in the bylaws.

COMMITTEE ON TRANSFERS

Continuing the work started last year by the committee on transfers, the effort again this year has been directed toward encouraging the Sections to maintain active transfers committees and toward providing all Sections with information on methods of operation which have been used with success as reported by individual Sections. To arrive at a best procedure to meet the needs of the greatest number of Sections has been the aim of the committee on transfers.

At the start of this fiscal year, the Institute made the committee on transfers a standing committee. This action aided materially in encouraging the Sections to establish their own transfers committees also as standing committees. Practically all Sections now actively and continuously are urging their qualified members to apply for high grades of membership. The necessary qualifications for each grade are more uniformly and generally understood.

The committee on transfers reported during the Sections committee meeting in Pittsburgh in January as part of the presentation, "The Model Section." That report said, in part:

> The activities of committees on transfers should not be of a campaign nature, in contrast with the work of membership committees. The work of transfers, consistently and continuously, year in and year out, should be to present the opportunity to qualified members to advance in grade of membership. . . . For the good of the individual and the welfare of the Institute it takes a group in each Section—"The Model Section"—to analyze its members and to encourage its qualified members to become what they should be in grade of membership. Our job is not to make members of higher grade but to present the benefits of the higher grades of membership to the extent that personal inertia is overcome. It is an honor to be an Associate. It is a higher honor to be a Member. It is the highest honor to be a Fellow of the AIEE.

On March 22, the committee on transfers and the Sections committee jointly sent a questionnaire to all Sections requesting pertinent information on their activities and experiences in transfers work. Reports on their most successful techniques also have been requested. Replies are coming in and will be correlated in a final report to be turned over to the succeeding committee on transfers of the Institute. If this report results in a generally acceptable and enduring plan of action for continuing grade transfers with minimum effort in the Sections, the primary aim of this committee will have been accomplished.

MEMBERSHIP COMMITTEE

In evidence of the active work carried on by Section membership committees during the past year, the total membership of the Institute increased to 28,400 on April 30, 1948—1,922 more members than enrolled for the same time last year. Table VI of membership statistics shows the nature of the changes in membership during the year. Mention should be made that the losses include 200 cases of nonresident members for whom inactive status had been maintained throughout the war period, who have not found it possible to become reinstated.

Applications for admission to membership received during the year totaled 3,753, a record figure for the Institute. Many of the applications still are pending, and all indications point to a steady growth in the membership total.

At the end of April 1947, 1,090 members were in arrears for dues, whereas this year the number had increased to 1,288. However, the increase amounts to less than one-half of one per cent of the membership total, and therefore is not significant.

The phenomenal growth in Student membership is shown in Table VIII, 13,917 persons being so enrolled with the Institute on April 30, 1948. From this source there should be a substantial increase in the membership of the Institute during the next few years.

The membership committee continued to encourage decentralization of its operations and increased activity on the part of the District vice-chairmen. At the beginning of the fiscal year, a recommended procedure of operation was sent out to all the District vice-chairmen for their guidance in handling membership activities in their Districts.

A small executive subcommittee of the membership committee was established. This subcommittee met at intervals of two months during the year and handled the general operational problems of the membership committee.

A membership committee meeting was held in Pittsburgh at the winter general meeting. At this committee meeting, presentations were made on the various problems connected with stimulating membership. This committee meeting was attended by a number of members of the membership committee and executives of the AIEE. Copies of the presentations were sent to all members of the membership committee so as to disseminate the new ideas which were presented.

A very active program was followed with all of the Sections to promote the advancement from Student to Associate grade. This program was very successful and the number of applications from Students this year exceeded all previous records. The membership committee continued its program of co-operation with Student Branches, and members of the committee presented talks on the benefit of AIEE membership before many of the Student Branches.

A subcommittee studying an alternative method of advancing Students to Associate membership continued to work with the committee on Student Branches in an effort to work out an improved method. It is planned to attach an application for the grade of Associate to the bill for Student dues which is sent to graduating seniors. In the letter transmitting this bill, the

				1948	28,400

seniors will be invited to apply for Associate membership immediately, and the processing of such applications will be delayed so that final action is taken at the time Student membership is about to expire.

A revised edition of a "Section Membership Committee Manual," was completed and sent out to all the Sections at the beginning of the fiscal year.

It is recommended that the membership committee in the future be made up of a chairman, vice-chairman, ten District vice-chairmen, and 13 members-at-large. The District vice-chairmen should serve a period of two years, with half of the group changing each year. Ten of the members-at-large should be former District vice-chairmen, and half of this group changed each year. The other three members-at-large should be liaison members from the board of directors, the committee on Student Branches, and the Sections committee. If this plan is followed in appointing the membership committee each year, the Institute will have the benefit of a maximum amount of experience on the committee, and be assured of a continuity of carrying out membership committee policy.

It also is recommended that appointees to the office of District vice-chairman have Section membership background.

Professional Group Committees

PROFESSIONAL GROUP CO-ORDINATING COMMITTEE

The committee co-operated with President Hull in selecting members for the several committees in the professional group.

A start was made toward closer co-ordination of the work of the committee on Student Branches and the committee on education. The problem of consolidation or closer co-ordination still is being studied and several joint activities are being considered.

Considerable correspondence was carried on between chairmen of the committees within the professional group regarding the proposal that the Institute join the co-operating organizations of the National Security Committee. A recommendation was agreed upon and submitted to the board of directors. This recommendation, which was adopted by the directors, was to the effect that, first, the Institute cannot take a stand on the subject of universal military training and, therefore, postpones the appointment of a representative to the National Security Committee, and, second, that the Institute is willing to work with any organization in the preparation of a training program to the end that the most effective use of technically-trained personnel is made.

COMMITTEE ON EDUCATION

A session was sponsored at the summer general meeting, with four educational papers. The committee will present a session at the 1948 summer general meeting featuring three papers, and, in co-operation with the committee on Student Branches, plans a joint session at the Midwest general meeting on the general theme of the electrical engineering profession. The intent of this meeting is to present sound information to the student membership concerning the profession.

Through the efforts of this committee, a plan for the publication of a "Bibliography of the History of Electrical Engineering," has been evolved. This material has been gathered by Professor T. J. Higgins over a period of many years, and represents a worthy addition to the history of electrical engineering.

Two members of the committee have been appointed to co-operate with the committee on Student Branches in drafting a program of common interest. This subcommittee is urged to study such topics as licensing of engineers, greater co-ordination between the various branches of engineering and professional aspects of engineering as a career, and any other such topics particularly applicable to the student engineer.

COMMITTEE ON STUDENT BRANCHES

A considerable number of inquiries have been processed concerning the operation of joint Student Branches, and requests were received for the establishment of new AIEE Student Branches. A new branch was established at Wayne University in Detroit during the past year, and a recommendation has been made to the board of directors for the establishment of one additional Branch outside of the continental limits of the United States.

At the meeting in Montreal, in June 1947, there was an extensive discussion of the criteria for the establishment of new Student Branches. The discussion centered primarily around the interpretation of the phrase, in section 64 in the bylaws, which reads "an established engineering society in a college or technical school of recognized standing may, upon application of its officers and a member of the Institute . . . . . become associated with the Institute." It was the consensus of opinion of those at this meeting that the term "recognized standing" should be defined as Engineering Council for Professional Development accrediting in so far as the establishment of new Student Branches was concerned, because the activities of ECPD are supported by the AIEE, and there seemed to be no other clear-cut criteria on which recommendations could be based. It was decided that ECPD accrediting should apply in the United States, and that outside, where ECPD accrediting is not in effect, an approximately equivalent standard would be required.

Work was carried on by a joint subcommittee between the membership committee

and the committee on Student Branches, to determine what could be done to encourage more Student members to become Associates upon graduation. A suggested procedure was presented at the winter general meeting by those members of this subcommittee who represented the committee on Student Branches. This suggested procedure has been submitted to all Student Branch counselors for a vote of approval or disapproval. The vote on this shows approximately ten to one for approval. The suggested procedure put up for vote read as follows:

A student may apply for Associate membership shortly before graduation. This may be done through an application form given by the faculty counselor or by the faculty counselor and a member of the membership committee from the local Section. The usual three references are required. This application will be transmitted to headquarters by the counselor upon graduation of the student and will be processed in the usual manner. The dues will continue at the Student rate until the expiration of the time limit for Student membership even though the member is now of the Associate grade. This would require revision of article IV, section 19 of the constitution.

In the event of arrears, that is, the member does not pay his Associate dues at the expiration of the time limit for Student membership rate or within three months thereafter, he will be placed on the suspended list and receive no further publications. This would require revision of section 18 of bylaws.

The present procedure also will remain in force as an alternate method of transfer from Student status to Associate grade. (Note this procedure at this time is only a proposal from the committee on Student Branches which at a later date may be forwarded to the board of directors. It is not now effective.)

The committee on Student Branches is assisting in re-editing the booklet "The Electrical Engineer" which is intended to orient and to guide high school students who are contemplating a career in electrical engineering.

The committee on Student Branches expects to enter into a co-operative arrangement with the committee on education, to sponsor a session at the Midwest general meeting in Milwaukee in October.

SPECIAL COMMITTEE TO REVIEW PRACTICES OF INSTITUTE PRIZE AWARDS

The draft of the proposed revised practice covering award of Institute prizes was reviewed with the board of directors and at the conference of vice-presidents and District secretaries in Montreal, in June 1947. After further revisions, the proposal was submitted to the board of directors and approved at the August 1947 meeting, at which time the special committee was discharged. The revised practices appeared in the December 1947, issue of *ELECTRICAL ENGINEERING*, and became effective January 1, 1948.

UNITED STATES NATIONAL COMMITTEE OF THE INTERNATIONAL ELECTROTECHNICAL COMMISSION

A considerable amount of technical work has been resumed actively during the year by the advisory committees of the International Electrotechnical Commission. The following meetings were held:

Group of experts on lamps, caps, and holders of advisory committee 6, London, May 1947

Advisory committee 30—extra-high voltages, Lucerne, October 1947

Advisory committee 12—radio communication, Lucerne, October 1947

Advisory committee 23—electric accessories, Lucerne, October 1947

International special committee on radio interference, Lucerne, October 1947

In addition, a meeting of the council was held in Zurich in June 1947, and of the committee of action in Brussels in October 1947.

The USNC was represented at all of the meetings. At the group of technical meetings held in Lucerne, it was represented by a strong delegation. At these meetings, all of which were the first technical ones since the war, substantial progress was made in getting under way the work of the advisory committees concerned. The European representatives are extremely anxious to meet with their colleagues from the rest of the world because during the war they had no opportunity to exchange information of a technical nature. They are anxious to press the work of the commission as much as possible, as they believe that this work will assist them in the many reconstruction and rehabilitation projects with which they are faced through war damage in their countries and through the demands of construction delayed during the war years.

The meetings of the council and the committee of action were concerned primarily with expediting resumption of technical work and with consummating the affiliation of the International Electrotechnical Commission with the International Organization for Standardization, as its electrical division. This affiliation now has been completed by its approval by the national committees. The central office of the IEC has been moved from London to Geneva where it occupies a building jointly with the ISO. It should be pointed out that the IEC retains its name, procedure, and freedom of action. It confidently is expected that this affiliation will give impetus and strength to the international standardization movement and that there will be important economics as well.

Meetings of the following advisory committees will be held in London and Paris in July, 1948

Advisory committee 30—Extra-high voltages
Advisory committee 31—Flameproof enclosures
Advisory committee 32—Fuses
Advisory committee 28—Co-ordination of insulation

The Swedish national committee has invited additional advisory committees to meet in Stockholm in October 1948. The committees which are to meet have not been definitely agreed upon.

During the year a reorganization of the electrical standards committee has been under way and has resulted in the addition of a number of new organizations in the field of electronics and communications. The membership of the ESC forms the nucleus of the USNC. While this matter was pending, no meeting of the USNC was held. Now that the membership has been completed, a meeting soon will be held. The work of the USNC has been carried out during the year by correspondence and through meetings of various technical advisory groups.

Technical Committees

Power Group

COMMITTEE ON ELECTRONIC POWER CONVERTERS

The status of this committee was changed, at the beginning of the 1947–48 administrative year, from a subcommittee of the electronics committee to a full committee in the power group. The membership was enlarged, and several liaison members from other committees were added.

Six subcommittees were established, as listed in the January 1948 issue of *ELECTRICAL ENGINEERING*. The organization of a West Coast subcommittee was initiated, and a chairman was appointed.

At the first meeting of the committee held in Pittsburgh on October 6, 1947, the subcommittees were organized, and the activities for the year were planned. A second meeting was held in Syracuse, N. Y., on May 17. Most of the subcommittees held meetings during the year.

A conference on the operation of mercury-arc rectifiers was held in Montreal on June 13, 1947, during the AIEE summer general meeting, under the sponsorship of the committee. Digests of the papers were published in the October 1947 issue of *ELECTRICAL ENGINEERING*.

A conference on mechanical rectifiers was held in Pittsburgh on January 29, 1948, during the AIEE winter general meeting, under the joint sponsorship of this committee and the electronics committee.

A working group of the committee has prepared a paper "Mercury-Arc Power Converters in North America," for presentation at the AIEE summer general meeting in Mexico City. The paper is a comprehensive report on the design and application of mercury-arc power converters.

The committee is planning to sponsor a conference on education in power electronics, in co-operation with other AIEE committees, to be held during the 1949 winter general meeting.

In addition to the committee activities outlined, several of the subcommittees carried on activities within their scopes.

Electronic Converter Application Subcommittee. This subcommittee is preparing questionnaire forms for collecting data on the operation and maintenance of mercury-arc rectifiers and on the characteristics of the a-c and d-c power circuits in rectifier installations. A working group was organized and started the preparation of a report on inductive co-ordination relating to the d-c circuits of rectifier installations. This report will be similar to the committee report "Inductive Co-ordination Aspects of Rectifier Installations," published in 1946, which dealt with the a-c systems of rectifier installations.

Electronic Converter Circuits Subcommittee. This subcommittee is preparing a report on protection of electronic power converters. The report is nearing completion, and it is planned to present it at the next Midwest general meeting of the AIEE.

Papers and Speakers Subcommittee. This subcommittee is preparing a bibliography on electronic power converters. The English-language section of the bibliography will be ready for publication this year.

Rectifying Devices Subcommittee. The chairman of this subcommittee is participating in the preparation of standards for mercury-arc pool-cathode tubes, which has been started under the sponsorship of the electron tubes subcommittee of the electronics committee. The subcommittee has not undertaken any independent activity.

Rectifier Transformers Subcommittee. This subcommittee is planning a comprehensive paper on the design and characteristics of rectifier transformers.

A proposal has been submitted by the chairman of the electronic power converter committee for enlarging the scope of the committee to include hot-cathode electronic converters, metallic rectifiers, and mechanical rectifiers, in addition to mercury-arc power converters. If this proposal is approved, the hot-cathode electronic converters subcommittee of the electronics committee and the metallic rectifiers subcommittee of the chemical, electrochemical, and electrothermal committee will be combined with the electronic power converter committee. It has been proposed also to change the name of the combined committee to "rectifier committee."

COMMITTEE ON CARRIER CURRENT

In this first year of operation, three full committee meetings have been held and in addition one meeting of subcommittee chairmen. Considerable time has been spent reviewing the activity of the previous joint subcommittee. It was decided to set up project subcommittees for the most important needs only and to retain other activities on file until additional personnel became available. Project subcommittees and status of work are as outlined in the following:

Preparation of an application guide. Work in progress.

Establish methods of measurements at carrier frequencies. Preliminary report circulated for comments. Expected to be ready for presentation as a technical paper in fall of 1948.

Obtain data on power system characteristics at carrier frequencies. Questionnaire sent out to obtain available test data.

Power equipment characteristics at carrier frequencies. Plans made for laboratory tests.

Report on features of traps and coupling capacitors for rural line carrier. Draft of report circulated for approval.

Report on microwave applications. Draft of report circulated for comments. Investigation of reliability of carrier relay channels questionnaire being prepared.

The committee did not sponsor any papers during the year. Plans are being developed for future technical papers and reports.

COMMITTEE ON POWER GENERATION

Concrete evidence of the committee's activities lies in the 13 papers presented at two meetings during the year. Practicality of the programs was attested by the large attendance that they attracted, and the extensive discussions that developed. The session sponsored by the committee at the Midwest general meeting in Chicago was devoted primarily to four papers on the determination of system generating capacity using the probability theory as a basis. The committee report on "Progress in Power Generation, 1940–46," also was presented at this time.

At the winter general meeting in Pittsburgh the power generation session was devoted to four papers on generator excitation systems and to four papers on hydraulic-turbine governor specifications.

The committee held meetings in conjunction with these two general meetings at which it organized its work for future technical sessions. Subcommittee activities reported at these meetings are briefed in the following:

Prime Movers. A symposium on gas turbines is in the process of organization planned for presentation at the next winter general meeting. Steps are being taken to co-ordinate work on a program for promulgating

recommended standardization of industrial steam turbines.

Speed Governing. This subcommittee working jointly with the American Society of Mechanical Engineers has issued two specifications to be used on a one year trial basis for steam turbines driving electric generators from 500- to 7,500-kw capacity, and for hydraulic turbines driving electric generators. Continuing efforts are being made in the solicitation of papers on prime-mover speed governing for general educational needs.

Excitation Systems. Papers are in preparation on excitation systems for presentation at coming meetings. The subcommittee now is working on an outline for "Definitions and Terminology on Excitation Systems for Synchronous Machines."

Station Design. Work is under way in organizing sessions on station descriptions and on automatic and supervisory control systems for central stations.

Hydroelectric Systems. Four papers have been arranged for presentation at the Pacific general meeting on the subjects of station bus arrangements, transmission line and switchgear connections, and pumping at various plants.

Other papers are in preparation for future meetings on the subjects of Grand Coulee and adaptation of generators to synchronous condenser service.

Pacific Coast. This subcommittee was organized to give a broader opportunity for members on the West Coast to participate directly in the organization of committee technical sessions. From several meetings of these members an extensive list of proposed subjects for future meetings was developed.

COMMITTEE ON RELAYS

In its first year of full committee status, the AIEE relay committee sponsored six formal papers, eight conference papers, and three conference sessions. The committee has contributed suggestions to assist with the expanded number and scope of technical committees and has engaged in joint projects with other committees. The principal technical activities were carried on through project committees, which are appointed to fulfill a specific assignment and discharged when the project is finished. In addition to three meetings of the full committee, practically all of the project committees have held one or more group meetings.

Generator Protection. To supplement previous information developed on the relay protection of generators, the project committee is making specific investigations of field protection, ground protection with high impedance neutral grounding, protection against motoring, tripping schemes for differential relays, and back-up protection. When these investigations are completed, the project committee findings will be summarized in a committee report.

Bibliography of Relay Literature. A formal paper, "Bibliography of Relay Literature—1944–1946," was presented (by title) at the January 1948 winter general meeting, and is being published in the *PROCEEDINGS*. This bibliography contains a list intended to include all technical articles published in the American and foreign press dealing with protective relaying. Collection of information is continuing so that another publication will be available, probably in 1950.

Co-ordination of Construction and Protection of Distribution Circuits (Joint Group). A study of the correlation of distribution circuit protection practices and construction methods, and the influence of these on the reduction of sustained faults, first was undertaken as a joint project of the (former) AIEE relay subcommittee and distribution subcommittee. The need for developing adequate performance records led to the expansion of the working group into one sponsored jointly by the relay committee and the distribution subcommittee of the AIEE, and the transmission and distribution committee of the Edison Electric Institute.

At a conference session held on January 27, 1948, in Pittsburgh during the winter general meeting, the performance of several distribution systems was summarized, with emphasis on schemes for instantaneous initial circuit breaker opening to protect sectionalizing fuses for transient faults, with subsequent time delay tripping to blow the fuses for sustained faults. Load inrush problems and ground relay protection also were discussed.

A survey is being prepared to obtain data on the relative operating characteristics and resulting degree of service continuity obtainable with various protection methods and construction practices; also, the presentation of formal papers is being encouraged.

Standards for Power Relays. The project committee on Standards for power relays has reviewed the comments and suggestions received following the circulation of a preliminary draft of a proposed revision of ASA Standard 6-37.1. A second draft of the proposed revision is nearly completed and will be circulated to the committee membership soon.

Insulation Levels for Relays and Control Circuits. The results of a survey conducted by the project committee appointed to study desirable insulation levels for relays and control circuits have shown that a test voltage of 1,500 volts alternating current should be adequate for the current, potential, d-c control, and tripping circuits of protective relays. Also, the need has been emphasized for close attention to the overvoltages introduced into control circuits by inductive "kicks" of closing solenoids,

The influence of relay contact spacing on breakdown voltage and on relay operating speeds is being investigated. A formal paper is being prepared outlining the basic factors of this problem and describing methods for suppressing transient overvoltages in relay and control circuits.

Sensitive Ground Protection. The project committee has collected information on available methods for sensitive ground relay protection of transmission and distribution circuits. Several methods used for transmission circuits and unigrounded distribution systems have been reviewed and the investigation of possible methods for improved sensitivity with 3-phase 4-wire common neutral circuits is being continued. A committee report should be available during the next administrative year, summarizing successful methods of sensitive ground protection of three wire systems and outlining the difficulties and limitations of schemes for four wire multigrounded neutral systems.

Transmission Line Protection. Analyses of a hypothetical, heavily loaded transmission system composed of short, medium length, and relatively long transmission lines have been made to crystallize the basic requirements of relay protective schemes and limitations of available methods.

In view of the increasing awareness of the need for improved transmission line performance required by the trend toward higher economic loading of lines, a conference session was held at the January 1948 winter general meeting. Three conference papers were presented at this meeting dealing with the relay protection of short, medium, and long transmission lines. This investigation is being continued along with the encouragement of formal papers.

Electronic Relay Applications. A survey of current practices has been made to determine the existing applications of electronic devices to protective relaying systems. The proper place of electronic devices in the protective relay field has been the subject of widely divergent views, some holding that they should be used whenever possible and others maintaining that applications should be limited to those functions which cannot be performed adequately by electromechanical elements.

To develop reasons for these divergent opinions a conference session was sponsored at the Chicago meeting of November 1947 with one introductory paper presenting the more favorable aspects of electronic relay applications and another covering general considerations including the limitations of such elements. It is believed that this subject warrants the presentation of formal papers and these are being encouraged.

Relay Performance of Current Transformers (Instrument Transformer Subcommittee). A new project committee was organized in September of 1947 to study the relaying performance of current transformers, with emphasis on the extension of methods for calculating the performance of those having high impedance secondaries. Attention also was directed to the wide variations in characteristics of auxiliary current transformers and certain main current transformers designed for mounting in the small space of metalclad switchgear.

As a result of a decision by the power co-ordinating committee, instrument transformers were placed under the scope of the transformer committee, and that committee organized an instrument transformer subcommittee with representation from the relay and other committees. Since December 1947, this project is being continued under the instrument transformer subcommittee.

Grounding of Instrument Transformer Secondary Circuits. Following the publication of a committee report on "Grounding of Instrument Transformer Secondary Circuits," in the April 1947 *ELECTRICAL ENGINEERING*, it has been agreed that the material should be converted into a form suitable for an operating guide and incorporated in the AIEE Standards. Since such a guide would be included most logically in the Standards on instrument transformers, the material and subsequent comments have been turned over to the instrument transformer subcommittee (of the transformer committee) for inclusion in the next revision of these Standards.

Relaying of Interconnections Between Industrial and Utility Generating Systems. A new project committee was organized in September of 1947 to investigate the special relaying problems encountered in the parallel operation of industrial generating systems with those of utility generating and transmission systems. The work is beginning with a survey of current practices.

Protection of Stations Without High-Voltage Switching. In September of 1947 a new project committee was organized to study various methods which might be used for the relay protection of stations and equipment which are not provided with high-voltage circuit breakers. The improved reliability of power transformers has led to the increasing use of

such schemes, and a survey to determine present practices is being undertaken.

COMMITTEE ON ROTATING MACHINERY

At the beginning of the 1947–48 Institute year the former committee on electric machinery was, under the new co-ordinating group organization, divided into several committees, one of which is the committee on rotating machinery. The first problem facing this newly designated committee was to organize so as properly to assume its assigned responsibilities. These included the previous functions of the electric machinery committee as related to rotating machines plus an expanded program to include classes of such machinery which it was felt previously had not been covered adequately. This organization took the form of a main committee with seven subcommittees—administrative, synchronous machinery, induction machinery, d-c machinery, single-phase and fractional-horsepower machinery, insulation, and test code.

The first meeting of the reorganized committee was held in Pittsburgh during the winter general meeting, January 1948. At that meeting, Mr. Steinberg, chairman of the power co-ordinating committee, gave a brief history of the new co-ordinating group activities and stated that after six months of operation, the organization is working well. He then asked for comments from the members of the rotating machinery committee as to their opinions both on the power group functioning and on their own committee activities. The general concensus of opinion indicated a very favorable acceptance of the entire new organization.

The machinery subcommittees then submitted reports on their activities:

Synchronous Machinery. A meeting was held at the winter general meeting at which recommendations were submitted for revisions of test code number 503, and suggestions made for better co-ordination among other codes and standards.

Induction Machinery. Similar actions with respect to codes and recommendations as for synchronous machinery.

D-C Machinery. A meeting was held during the Chicago meeting and another during the midwinter meeting. The program for more accurate loss evaluation and temperature determination by test is proceeding, and recommendations incorporating the results of the program in various test codes and standards will be made. A carbon brush test code is in process under joint sponsorship of this and another committee.

Single-Phase and Fractional-Horsepower Machinery. This is a newly organized subcommittee. The committee plans to study the proper scope of its activities as co-ordinated with other subcommittees, the preparation of test of codes, and the submission of recommendations for standards.

Insulation. A meeting was held at the winter meeting at which time a preliminary draft of the proposed Standards on insulation resistance of d-c machinery was discussed. It was decided to rewrite completely AIEE Standard 43 to include d-c machinery.

Following the submission of these reports, the main committee discussed them and other business. The scope of the insulation subcommittee was broadened from its previous activity of insulation resistance to cover all proper types of activity on rotating machinery insulation. The main committee was informed of and approved an ambitious program to prepare an extensive bibliography on rotating machinery which would be submitted to the Institute as a basis for reference and for analysis of the published literature. The preparation of the application guides by the rotating machinery committee was deemed undesirable, however co-operation with industry committees will be undertaken gladly should they desire such guides. Business pertaining to joint action between the rotating machinery and other committees was discussed with recommendations for action.

During the period up to April 30, 1948, the committee as a whole, through its subcommittees, has sponsored six technical sessions including a major motor program at the Middle Eastern District meeting at Dayton. In all, 33 technical papers have been sponsored at four major meetings. AIEE Standard 43 has been written. Report *43-A*, "Recommended Practice for Insulation Resistance Testing of Rotating Machinery," soon will be ready for submission. Plans have been made for sponsoring a major rotating machinery meeting during the coming year.

COMMITTEE ON SYSTEM ENGINEERING

This committee is a new technical committee established by the reorganization of the technical committees of the power group for this year. In view of this, a completely new committee organization had to be set up. There was no committee work or investigations carried over from the previous year as is the usual case with standing committees. In the formation of the committee, a definite attempt was made to secure as country-wide representation as possible and this also was carried out in the establishment of the subcommittees. There were six subcommittees established as follows: administrative, system planning, system operations, system economics, system controls, and interconnection contracts.

The scope for the system engineering committee was reported in the October 1947 issue of *ELECTRICAL ENGINEERING*. The membership and scopes of the subcommittees were given in detail in the January 1948 issue of *ELECTRICAL ENGINEERING*.

The first meeting of the system engineering committee was held on November 5, 1947, in Chicago, Ill., during the Midwest general meeting with 18 members or their representatives in attendance. The scopes and memberships of all the subcommittees were given a final review and assignments were made to the individual subcommittees as to investigations and solicitation of papers for future AIEE meetings.

A second meeting of the system engineering committee was held on January 29, 1948, in Pittsburgh, during the winter general meeting with 21 members and guests present. At this time the individual subcommittees reported as to their work and their plans in progress. Plans were made for solicitation of papers for presentation at the Midwest general meeting in the Fall of 1948. It was announced that a joint subcommittee had been appointed on the "application of probability methods to capacity problems." This is to be a joint subcommittee with the power generation committee.

A general system engineering session was sponsored at the winter general meeting in Pittsburgh, at which five conference papers were presented. The first of these was on the timely subject "Electric Power and Our National Defense." The other four conference papers were a symposium on the "Controllable Factors Affecting System Loads." These were believed to be of importance in view of the tight capacity conditions existing throughout the United States at present.

A special subcommittee has been established under the sponsorship of the switchgear committee to investigate "high-voltage switching where out of phase voltages exist at time of arc interruption." The system engineering committee, together with the power generation, relay, and transmission and distribution committees, is providing for representation on this working subcommittee.

At the time of rendering this report, the several subcommittees have in preparation technical papers for at least two and probably three full sessions at the Midwest general meeting in Milwaukee, October 18–22, 1948.

The system controls subcommittee is preparing a questionnaire to be sent to operating companies to summarize the status of load-frequency control equipment and its use on the various individual and interconnected systems. It is expected that this report will be available for the Milwaukee meeting.

COMMITTEE ON TRANSMISSION AND DISTRIBUTION

Since the reorganization of the technical committees and reallocation of scopes, three meetings of the transmission and distribution committee have been held, the first on December 5 in Chicago, the second on February 25 in Cleveland, the third on May 28 in New York. The meetings were well attended. Following the formal meeting in Cleveland a general discussion organized previously by the lightning and insulator subcommittee was held on the subject of insulator contamination. Two prepared discussions were presented after which a general discussion followed.

Technical Meetings. Two technical sessions were sponsored by the transmission and distribution committee at the Midwest general meeting at which papers dealing with the Tidd 500-kv project were presented. A joint session at this meeting also was sponsored by the transmission and distribution committee. At the winter general meeting a session dealing with the Duquesne Light 10,000-kva series capacitor was sponsored. Two technical sessions sponsored by the transmission and distribution committee are being held at the Mexico City meeting.

Capacitor Subcommittee. The capacitor subcommittee is engaged in the revision of AIEE Standard 18 on capacitors. A final draft of the proposed Standard will be completed this year. This subcommittee also is concerned with operating procedures and application requirements for capacitors and is investigating troubles that have occurred with capacitors.

Distribution Subcommittee. The principal activity of the distribution subcommittee was concerned with the preparation of a report entitled "Distribution Design Practices and Trends," to be presented at the summer general meeting. This subcommittee also has in mind the organization of a symposium during the 1949 winter general meeting on the "Operation of Primary Network Systems." Consideration also is being given to the question of sag data for distribution conductors.

General Systems Subcommittee. The general systems subcommittee has completed a report on "Power System Recovery Voltages." A working group of this subcommittee actively

is engaged jointly with the lightning protective devices subcommittee of the protective devices committee in the determination of "the voltage recovery of typical distribution circuits."

Lightning and Insulator Subcommittee. This subcommittee has under preparation a report entitled "Recommendations for Lightning-Proof Lines." They also actively are sponsoring papers concerned with insulator contamination and corrective measures. A symposium on this subject is being organized for the Midwest general meeting. This subcommittee also is concerning itself with the development of additional data on 60-cycle and impulse flashover characteristics of disk-type insulator strings made up of between 20 and 30 units. This is for use in connection with transmission voltages in the range of ultrahigh voltages.

Towers, Poles, and Conductors Subcommittee. A report has just been completed by this subcommittee entitled "Conductors—Types, Availability, and Use," which will be presented at the summer general meeting. Other subjects being considered by this committee are the thermal limitations of conductors and clamps and radio interference emanating from corona.

Co-ordination with Edison Electric Institute. An effort is being made to engender closer co-operation between the transmission and distribution committee of the EEI and transmission and distribution committee of the AIEE. To this end a proposal is being considered to have mutual representation of responsible officers on the respective committees. A striking example of this co-operation is the organization of the subject committee on line outages of the transmission and distribution committee of the AIEE, in which the EEI committee will be represented officially by a member. The function of this committee is to collect information on various phases of line outages. The EEI representative will report the progress of the EEI committee and operate in a general liaison capacity. Similarly, with regard to the study being made by the capacitor subcommittee with relation to capacitor troubles, Howard Stites is the EEI representative on this committee work.

Industry Group

COMMITTEE ON CHEMICAL, ELECTROCHEMICAL, AND ELECTROTHERMAL APPLICATIONS

The committee held one general meeting during the year, in Pittsburgh, January 1948. The accomplishments of the past calendar year were reviewed and plans discussed for the coming year.

A new subcommittee on chemical industries was formed and some personnel appointed. The scope of this subcommittee is to cover the interests of the chemical industry exclusive of electrolytic or electrothermal processes.

It is believed that this technical committee now is organized logically into its functional subcommittees, and personnel and chairmen have been secured. The subcommittees now are functioning.

This technical committee consists of the following subcommittees:

1. Electrolytic processes
2. Batteries, battery forming, and charging
3. Arc furnaces and electrothermal processes
4. Metallic rectifiers
5. Petroleum refining and production
6. Cathodic protection
7. Chemical industries

The special subcommittee on voltage transients in arc furnaces has died without issue.

The following activities were engaged in during the year by the subcommittees:

1. *Electrolytic processes*

Held a conference on conversion equipment in the electrochemical industry in Montreal, June 1947. Conference papers published in booklet form together with formal papers sponsored by power electronics group.

Held a meeting of this subcommittee in Montreal and discussed future plans.

2. *Batteries, battery forming, and charging*

Held a conference on the care, maintenance, and charging of storage batteries in Chicago, October 1947. The meeting of the subcommittee discussed possible future activities and work that needs to be done.

3. *Arc furnaces and electrothermal processes*

Held a conference on electrothermal processes in Pittsburgh, January 1948. Several of these conference-type papers are being prepared for publication.

4. *Metallic rectifiers*

A subcommittee meeting was held on October 11, 1947, in New York to discuss plans for the 1948 winter general meeting.

Held a conference in Pittsburgh, January 1948, with one formal paper and five conference-type papers. The subcommittee also held a committee meeting to discuss Standards for metallic rectifiers and to plan future activities. The proposed Standard for metallic rectifiers was published for comments and criticism on August 1, 1946; revised December 2, 1946, April 18, 1947, June 9, 1947, and July 1947.

5. *Petroleum refining and production*

While no formal meeting of the subcommittee yet has been held, two formal papers are being sponsored for the Mexico City meeting.

COMMITTEE ON ELECTRIC HEATING

The board of directors authorized in January 1947 the formation of a technical committee on electric heating. During the past year this committee has been organized and its work initiated with the assistance of several subcommittees. These subcommittees include the following: electronic heating, radiation measurements above 200 megacycles, resistance heating and electric furnaces, and radiant heating. The first meeting of the electric heating committee was held on January 27, 1948, in connection with the 1948 winter general meeting. The committee sponsored a session at this meeting on electronic and resistance heating.

The work of the subcommittee on electronic heating on interfering radiations from induction and dielectric heating equipment has been continued. Upon the advice of this subcommittee the Federal Communications Commission has promulgated rules and regulations regarding interference from such equipment. A working group of the subcommittee now is engaged in studying the matter of good engineering practice in the case of interference. Another working group has initiated the preparation of Standards on induction and dielectric heating. Because of the interest of Institute of Radio Engineers and National Electrical Manufacturers Association in these matters it was thought advisable to form a joint co-ordination committee to distribute the work among the committees of the various interested societies. This committee is known as the joint AIEE, IRE, NEMA co-ordination committee on commercial induction and dielectric heating apparatus. The AIEE representative on this committee is the chairman of the electric heating committee.

The subcommittee on radiation measurements above 200 megacycles has studied equipment and methods for measurement of radiation in the frequency range from 200 megacycles to 20,000 megacycles. This work, of course, is in preparation for the extension of dielectric heating into this frequency range. The techniques and equipment used for such measurements differ widely from those employed at lower frequencies, so that much original work has been required which eventually will be presented to the members of AIEE in papers.

The subcommittee on resistance heating and electric furnaces held its first meeting in connection with the 1948 winter general meeting of AIEE. It plans active participation in a program to stimulate and standardize this form of heating in industry.

The subcommittee on radiant heating held its first meeting in February 1948. It plans an unusually large program covering the following: historical, methods of temperature measurement, Standards, coatings for infrared baking, patents, energy distribution, control equipment and safety, research, and Student Branches.

COMMITTEE ON INDUSTRIAL CONTROL

The scope of this committee has been broadened to include design, construction, and performance of industrial control equipment. Some progress has been made in increasing the number of industrial engineers in the membership of the committee.

The subcommittee on Standards actively is engaged in the revision of the present AIEE industrial control Standard in co-operation with the corresponding committees of American Standards Association and NEMA. A revised draft of the Standard soon will be ready for the Standards committee.

The subcommittee on electronic control has had an active year organizing its various working groups with a view to preparing circuit and component definitions associated with industrial electronic control. This subcommittee is represented on the committee on electronics and its work is being correlated closely with the more general committee. The working groups have defined their objectives which, when completed, should extend the usefulness of the present AIEE Standard on Industrial Control.

The subcommittee on test codes is proceeding with one or two projects which are part of an over-all program established during the year.

The bibliography continues to grow, and it is hoped that before long a completely indexed bibliography of extensive proportions will be available for publication.

The joint subcommittee on servomechanisms continues to act under the joint sponsorship of the committees on basic sciences and instruments and measurements. An interesting session was held at the winter general meeting. The activities of the subcommittee on electronic control is being correlated with this joint subcommittee to prevent overlapping. It is hoped that the joint subcommittee will sponsor more papers illustrating the application of servomechanism theory to industrial problems.

During the year the committee has been very actively engaged in soliciting papers. One session was sponsored at the 1947 sum-

mer general meeting, one at the Midwest general meeting, and two on steel mill applications at the winter general meeting, and another on wire drawing machinery at New Haven in April 1948. The sessions were well attended and brought considerable discussion from the membership.

Communication and Science Group

COMMITTEE ON COMMUNICATION

The communication phase of electrical engineering as practiced today covers a very broad and continually expanding activity. The committee on communication is constantly on the lookout for papers of interest to the specialist in communications, as well as papers of general interest to the electrical engineer. Special attention has been given to papers on radiobroadcasting and home receivers. Several sessions are being scheduled at the 1948 Midwest general meeting covering these subjects.

Full sessions were sponsored by the committee at all of the general meetings. Two sessions composed of eight papers were sponsored at the summer general meeting in Montreal. One session included papers on modulation, and the other the general subject of communication. At the 1947 Pacific general meeting held in San Diego, two sessions composed of 11 papers were sponsored by the committee. The papers covered the fields of communication, electronics, and Sonar. Two sessions composed of eight papers covering general and special communication subjects were presented at the Chicago Midwest general meeting. An extra effort was made at the Pittsburgh winter general meeting to highlight communication subjects. As a result, five sessions composed of 17 papers covering communication components and techniques, magnetic recording, synthetic crystals, facsimile, and radio relay systems were presented.

As the current fiscal year draws to a close, plans have been finalized for a 4-paper session at the Mexico City summer meeting and a 4-paper session for the Spokane general meeting. A 20-paper 5-session program is in the preliminary planning stage for the Milwaukee Midwest general meeting.

Papers solicited and reviewed by the committee are available for use at District meetings. Two requests for communication papers were received from Districts during the current fiscal year.

During the year 21 papers and reports sponsored by the committee were published in *ELECTRICAL ENGINEERING* or in *TRANSACTIONS*. Many more have been recommended for future publication.

Starting in August 1947, the committee on communication was reorganized. Nine subcommittees were appointed and cover the following fields:

1. Wire communication systems.
2. Radio communication systems.
3. Radiobroadcasting systems.
4. Communication switching systems.
5. Power line carrier systems.
6. Home radio receivers.
7. Record communication.
8. Special communication application.
9. Communication standards.

The subcommittee chairmen, committee chairman, vice-chairman, secretary, and junior past chairman, have composed a co-ordinating committee to direct, in general, the subcommittee activities and take final action on matters referred to the committee for attention. Two general meetings of the whole committee and three meetings of the co-ordinating committee have been held during the current fiscal year. The purpose of the foregoing reorganization is directed toward communication group status with full committee responsibility for the present subcommittees.

COMMITTEE ON COMPUTING DEVICES

The committee on computing devices was newly formed in January 1948. Most of the work has been as a subcommittee of the basic sciences committee. (There was a conference at Montreal, and a few papers published in *ELECTRICAL ENGINEERING*.)

The only committee activity has been organizational, that is, to appoint a vice-chairman (Doctor J. G. Brainerd) and a secretary (Professor W. C. Johnson), and to form two subcommittees, one on digital computers (Doctor J. W. Mauchly, chairman), and one on continuous-variable computers (Doctor E. L. Harder, chairman).

COMMITTEE ON BASIC SCIENCES

The committee on basic sciences occupies a unique position in the activities of the Institute. Its function is to advance the theory of electrical engineering and of the allied arts and sciences in all of their branches; consequently, efforts have been, and are being made, to assist the several other technical committees wherever such action is desired. Specific examples which may be mentioned are: the initiation of nucleonic studies by the subcommittee on energy sources, which subject subsequently was taken over by the full technical committee on nucleonics; formation of a joint subcommittee on servomechanisms, with the committees on instruments and measurements, and on industrial control devices; subcommittee on large scale computing devices, recently transformed into a full technical committee on computing devices; liaison members on subcommittees of the committees on electrochemistry and electrometallurgy, on systems engineering, and on power generation.

The subcommittee method of operation of the committee on basic sciences has proved to be highly successful during the past two years of its operation. It had been suggested by the preceding chairman of the committee during the war, but military restrictions at that time limited the activities of the committee, causing postponement of the program.

During the past year, the committee and its several subcommittees have held sessions, conferences, and symposia in their respective fields, as follows:

Summer General Meeting (Montreal), June 1947

1. Participation in conference on technical group activities in the Sections.
2. Session on servomechanisms.
3. Conference on large scale computing devices.

Midwest General Meeting (Chicago), November 1947

1. Conference on energy sources.
2. Session on basic sciences.

Winter General Meeting (Pittsburgh), January 1948

1. Session on basic sciences.
2. Conference on applied mathematics.
3. Symposium on electrical network theory.
4. Session on servomechanisms (combined with measurements).

The interest shown at these meetings has been quite gratifying, in most instances being among those sessions having the largest attendance at the technical meetings.

Four subcommittees have been in active work during the past year. These are: electric circuit theory, energy sources, applied mathematics, and large scale computing devices. As mentioned, the subcommittee on large scale computing devices has become a full technical committee, retaining the same personnel as that of the subcommittee. Two new subcommittees have been formed in the past few months, and a third is planned. Those now underway are the subcommittees on electrical properties of solids and on magnetics. The third is to be the subcommittee on electrical properties of liquids and gases. It is expected that these new subcommittees will be in a position to conduct conferences in their respective fields, beginning with the 1949 winter general meeting of the Institute.

As a number of the committee members also are members of subcommittee 1 of ASA sectional committee *C-42*, "Definitions of Electrical Terms," it is planned to establish definitions of fundamental and derived terms which are acceptable to the engineering profession as a whole. The committee on basic sciences will provide the desired reviewing body for this work.

As it is extremely difficult to hold committee meetings at frequent intervals, because of the wide dispersion of the membership, it has been the practice to hold committee meetings in connection with the general meetings of the Institute. The attendance at these meetings has been very good, which along with the correspondence among members, has enabled the committee to function quite efficiently.

COMMITTEE ON ELECTRONICS

The committee has continued the policy of subcommittee rotation, that is, of forming and disbanding, as needs require, subcommittees in various fields of electronic design and application. The purpose of this policy is to insure active AIEE contact and support in all areas of the expanding electronic arts; it calls for occasional upgrading of major subcommittees to the status of technical committees of the Institute.

There are two types of subcommittees within the committee organization. One type serves to expedite general functions, including: processing of Standards; papers solicitation and aids to Sections; maintenance of nation-wide and international informational contacts; education; and liaison with other professional groups. The other type is responsible for attention to specific technical fields. The committee entered the year with five general-function subcommittees, and added three, thus closing the year with eight such groups. At the beginning of the present administrative year there were six subcommittees having specific technical activities; and five new ones were formed; thus the electronics committee closes the year with a total of 19 subcommittees of which number 8 are administrative and 11 are technical.

Plans of operation for the 1947–48 period were formulated at a meeting of subcommittee chairmen in New York City on

August 26, 1947. A meeting of the committee was held in Chicago on November 4, 1947, in connection with the National Electronics Conference, where procedures involved in establishing Standards were discussed in some detail. A meeting held at Pittsburgh on January 26, 1948, in connection with the winter general meeting, was devoted to reviews of plans for technical sessions, conferences, and papers, and to reports on the accomplishments of the various subcommittees during the year past.

At the 1947 summer general meeting in Montreal the committee sponsored a technical session, and a conference on rectifiers. The committee organized a technical session of the National Electronics Conference at Chicago on November 4. At the winter general meeting in Pittsburgh the committee sponsored a technical session, also a technical conference on, "Some New Electronic Devices and Methods," also, the committee shared with the rectifier committee the sponsorship of a conference on mechanical rectifiers. For the summer general meeting in Mexico City the committee has arranged two technical papers, and has assisted the committee on education in arranging a discussion of certain educational aspects of electronics.

Through the medium of the joint subcommittee on electronic instruments, the committee had an important share in the planning of the 2-day AIEE conference on electron tubes, held in Philadelphia, March 29 and 30. The objective of this conference was to study the problem of making generally available electron tubes meeting specifications needed for electronic instruments and related industrial electronic devices. This conference consisted of five technical sessions, the three on the first day being devoted to study of the factual background of the problem, and those on the second day to methods of meeting the existing needs. The conference was very well attended; there was active discussion; and it is believed the program was an important contribution.

During the calendar year 1947, *ELECTRICAL ENGINEERING* contained a very large proportion of articles including important electronic material. The activities of the committee and its subcommittees have contributed substantially to this result.

Activities of the subcommittees of the general-function type are reported in the following.

Electronic Papers Solicitation and Section Contacts. This subcommittee continually has solicited technical papers from the other subcommittees. It has provided a convenient channel for originating and selecting suitable papers, and for organizing technical sessions relative to all fields of electronic application. This subcommittee sponsors annually at the winter general meeting a conference on new electronic devices and methods. Active encouragement has been given to other technical committees of the Institute to sponsor electronic papers at appropriate technical sessions.

Sections of the Institute have been aided materially by this subcommittee's activity in providing films, speakers, and technical information on electronic subjects.

Standards. This subcommittee keeps the committee members informed as to standardizing procedure, also as to the progress of specific standard proposals, and serves as a channel for processing Standards. It is at present active in attempting to establish a uniformity between American Standard symbols and those recommended by the Patent Office, in regard to electronic diagrams. This subcommittee is maintaining contact with certain IRE committee activities of importance in regard to Standards in radar and frequency designation.

Liaison With IRE. It is essential to maintain proper contact and co-ordination of committee activity between various professional groups active in electronic matters. It is this subcommittee's responsibility to maintain an awareness of co-ordination needs, particularly relative to the IRE.

Liaison With Joint Electron Tube Engineering Council. It is important that the committee be kept informed of the needs and interests of the JETEC in matters of policy, co-ordination as to area of standardization, and so forth. This liaison has been provided by the subcommittee on liaison with JETEC.

Liaison With Nucleonics. Most of the instruments and apparatus employed in neucleonics are electronic in character. This liaison committee was formed to keep the electronics committee informed of the work of the neucleonics committee.

Electronic Developments Abroad. This subcommittee has prepared a survey report of recent progress in power electronics in several European countries, including extracts from extensive foreign reports received in reply to the subcommittee's inquiries. The information relative to new uses of d-c transmission is of special interest. This report should appear in an early issue of *ELECTRICAL ENGINEERING.*

Education in Electronics. This newly-formed subcommittee will acquaint the committee with progress and problems related to rapidly changing requirements for education in the electronic areas of electrical engineering, and co-ordinate the committee's activities with those of the AIEE committee on education.

West Coast Subcommittee. This newly-formed subcommittee will be concerned with securing papers of electronic interest from the West Coast area, particularly for meetings in that area, and with stimulating active participation from that area in AIEE technical committee work, where electronic problems are involved.

The activities of subcommittees working in specific technical fields may be summarized as in the following:

Electronic Instruments. The joint committee on electronic instruments completed its survey of special tube needs for instrumentation purposes, and organized the afore-mentioned 2-day tube conference. Participation in this survey and conference activity has been one of the most important contributions of the committee on electronics during the past year. This activity is being continued. Five technical papers and three conference papers were obtained for the Pittsburgh meeting by this subcommittee; the technical papers are being processed for publication. A program of Standards work in the electronic instrument field is being formulated.

Electron Tubes. The scope of this subcommittee is the treatment of all appropriate technical matters relating to the design, construction, test, and operation of electron tubes for industrial use, including the preparation of Standards, papers, and reports, and the promotion of meetings and conferences dealing with electron tubes and their uses. All classes of electron tubes important for industrial use are included in the intent of this scope.

Four working groups have been organized to give immediate attention to the preparation of Standards for tubes used industrially. The working groups deal respectively with high vacuum tubes, cathode-ray tubes, gas-filled tubes and photoelectric tubes, and mercury-pool tubes. The initial meetings of the various working groups were held during the early months of 1948.

Electronic Aids to Medicine. This subcommittee is planning a 2-day conference, to be held in New York City in the Fall of 1948. Arrangements are being set up to attract both engineering and medical personnel, in order to promote a better understanding by engineers of the engineering problems peculiar to biological practice, and by medical personnel of possible engineering approaches to biological practice. Subjects discussed at the conference will include biological amplifier and recording device requirements, practice in biological stable isotope measurements, and present practice in biological radioactivity measurement.

Electronic Aids to Navigation. This subcommittee operates jointly with an IRE committee on the same subject. This group has compiled a set of more than 200 basic definitions of radio navigation terms which currently are being compared, for purposes of mutual revision, with a set of similar definitions by the Radio Technical Commission for Aeronautics.

High-Frequency Conductors, Cables, and Connectors. The scope of this subcommittee is to give attention to Standards, papers procurement, and so forth, to the developing needs for adequate handling of power and signals in high-frequency coaxial and wave guide circuit elements, including problems of heating, reflection, and impedance characteristics.

Hot Cathode Converters. This subcommittee has completed its immediate Standards program on definitions, except for the adjustment of a few inconsistencies between American Standard Definitions and proposed Standards for mercury arc power rectifiers and for metallic rectifiers. The committee now is compiling a list of circuits to be included in the Standards. The committee is endeavoring to procure technical papers which will clarify existing uncertainties as to test code basis in hot cathode rectifier equipment in which transformer reactance is important.

X-Ray Tubes and Apparatus. This committee recently has been reorganized, to broaden its scope. This group currently is reviewing recently proposed Standards, and is studying means of specifying X-ray and associated rectifier tube characteristics and ratings. Arrangements have been made for co-ordination of the Standards activity with the work of NEMA and Radio Manufacturers Association groups having similar interests.

Electronic Precipitation. This subcommittee is planning papers for a technical session on electronic precipitation equipment, with a later one in prospect relative to electrostatic phenomena in industry.

Electronic Aids to Geophysics. The immediate objective of this recently formed subcommittee will be to give AIEE support to efforts being made, by co-ordinated technical societies in the oil-producing geographical area, toward broader publicizing in technical periodicals of the many recent important developments in this field of interest.

Infrared Applications. This subcommittee has been very recently formed, and is at present making a study to outline its scope and immediate objectives.

Electronic Preparation and Preservation of Food. This subcommittee's present status is the same as that on infrared applications.

The committee, as a whole, is attempting to maintain a vigorous outlook to insure adequate coverage of the various fields in which electronics is becoming of importance in science, industry, and government.

COMMITTEE ON INSTRUMENTS AND MEASUREMENTS

The activities of this committee have been directed toward the fostering of interest, the co-ordination of effort, and the development of Standards in the field of measurements which underlies so much of the technical activity of the Institute. To secure adequate representation in some of the newer phases of measuring activity, and provide closer liaison with other technical committees, the membership of the committee was expanded to 41. Meetings of the main committee were held on October 21, 1947, and March 16, 1948, and there have been numerous meetings of subcommittees.

A total of 25 technical papers sponsored by the committee were presented during the year, and most of these are being published. These papers cover a wide range of subject matter, including: fundamental analyses of measuring methods; microwave frequency measuring devices, methods, and Standards; new types of telemetering systems; oscillograph and oscilloscope techniques; industrial electronic instruments for steel processing; laboratory measuring standards; d-c amplifiers and other electronic circuits; nucleonic instrumentation; calorimetric measurements; characteristics of recording instruments; optical radar; supersonic devices; instrument characteristics; recording of sea water characteristics.

The committee sponsored two technical sessions at the winter meeting and was joint sponsor for three others. Additional papers were presented at the Great Lakes and North Eastern District meetings.

A large part of the work is carried out through nine subcommittees.

Subcommittee on Revision of Standard 4 (Measurement of Test Voltage in Dielectric Tests). A working group is drawing up a specification for measurements of surge voltages at intervals from 0.1 to 1 microsecond. Additional material is being prepared on other measuring methods.

Subcommittee on Revision of C39 (Electric Indicating Instruments). This subcommittee is co-operating with the ASA subcommittee on a complete revision of the *C39* standard. The work on panel-type and switchboard instruments is substantially complete and will be presented for approval at an early date. Consideration of portable instruments and laboratory Standards will follow.

Subcommittee on Master Test Code for Resistance Measurements. A proposed new code was published in September 1947 for one year's trial use. Comments are being collected.

Subcommittee on Master Test Code for Temperature Measurements. At the suggestion of the Standards committee, a proposed new code has been circulated for comment. It now is being presubmitted with the recommendation that it be printed for trial use.

Subcommittee on Marking of Varmeters and Related Instruments. A questionnaire is being circulated to determine types of instruments and their markings.

Subcommittee on Watt-hour Meters. Activities were limited to minor standardization matters.

Subcommittee on Electrical Tests on Dielectrics in the Field. A general report and bibliography on this subject are being prepared. A technical conference is planned for the Milwaukee meeting in October 1948.

Subcommittee on High-Frequency Measurements. The field of this subcommittee includes all frequencies above the audio range, with special emphasis on the higher radio frequencies where the more recent developments in the art are found. A technical session was sponsored at the winter meeting. A symposium is planned under the joint sponsorship of AIEE, IRE, and Bureau of Standards.

Subcommittee on Definitions. A large number of definitions prepared by this subcommittee have been transmitted to appropriate subcommittees of ASA *C42*. Definitions prepared by Subcommittee 6 of ASA *C42* are being reviewed by this subcommittee.

Close relationship and co-operation with other technical committees is fundamental to the work of the committee on instruments and measurements. Co-ordination is maintained by a number of joint subcommittees, and in other cases by cross representation. During the year, one new joint subcommittee was formed to centralize all Institute work on instrument transformers. This is under the direction of the instruments and measurements committee and the transformer committee, with representation also from the switchgear committee, the relay committee, the transmission and distribution committee, and the carrier current committee. For better co-ordination, the chairmen of all the standing joint subcommittees have been made members of the instruments and measurements committee.

Joint Subcommittee on Electronic Instruments. This subcommittee completed its survey of the needs and requirements for improved electron tubes for industrial instrumentation and control. A 2-day conference was held at Philadelphia to present the results of the survey and outline a program for obtaining improved tubes. A registration of 281 attested to the success of this conference. Contributing largely to this success was the community of interest in the subject. The conference has given a needed impetus to improved tubes for industrial usage, and should have important results in future. Moreover, it has established a pattern which other committees are planning to follow.

Joint Subcommittee on Servomechanisms. This subcommittee has been reorganized. Two technical papers were presented at the winter meeting.

Joint Subcommittee on Nucleonic Instruments. A conference session on instruments for radiation measurement was sponsored at the winter meeting, and similar sessions are planned in August and October. A paper on "Methods of Protection and Measurement of Nuclear Radiation," was published.

Joint Subcommittee on Telemetering. The October 1941 report on telemetering, supervisory control, and associated circuits is being revised. A technical session was sponsored at the winter meeting.

Joint Subcommittee on Instrument Transformers. This newly formed subcommittee has organized working groups to handle activities on current transformers, test code, and rating factors. That part of the new Standard ASA *C57* which deals with instrument transformers is being published separately by the AIEE.

Joint Subcommittee on Standard Frequency Bands and Designations. A proposed table of standard frequency bands was published in *ELECTRICAL ENGINEERING*. Co-ordination with IRE, looking toward an ASA Standard, now is required.

COMMITTEE ON NUCLEONICS

Three meetings of the committee were held—one each in Montreal, Chicago, and Pittsburgh. At the Chicago meeting, the committee sponsored a talk by Doctor Enrico Fermi on the "Future of Atomic Power." The Des Moines District meeting had one session with four papers devoted to the subject of particle accelerators. The Pittsburgh meeting had a session of five conference papers on nucleonics instruments.

A series of papers on nucleonics were sponsored by the committee for publication in *ELECTRICAL ENGINEERING* as follows:

1. "The Atom and Its Nucleus," J. J. Smith (*EE, Dec '47, pp 1165–75*)
2. "The Relation Between Energy and Mass," Frederick Seitz, Jr. (*EE, Jan '48, pp 1–5*)
3. "The Nucleus—Its Structure and Reactions," W. E. Shoupp, Hugh Odishaw (*EE, Feb '48, pp 125–34*)
4. "Nuclear Engineering," E. U. Condon (*EE, Mar '48, pp 229–32*)
5. "Detection and Measurement of Nuclear Radiation," G. Wesley Dunlap (*EE, Apr '48, pp 325–32*)
6. "The Separation of Isotopes," G. Wesley Dunlap, R. M. Lichtenstein (*EE, May '48, pp 469–74*)
7. "Cascades Used in Isotope Separation," Harold C. Urey (*EE, Jun '48, pp 581–6*)
8. "Nuclear Reactors," F. L. Friedman (*EE, Jul '48, pp 685–93*)
9. "High-Energy Particle Accelerators," J. R. Woodyard (*EE, Aug '48, pp 759–67*)

The following articles are planned to complete the series:

10. "Physical and Medical Aspects of Radiation Hazards and Protection," L. L. German, H. M. Rosendaal
11. "Isotopic Tracers," J. T. Wilson
12. "Nuclear Reactors for Power Generation," W. F. Davidson

The purpose of this series is to furnish members of the Institute with an over-all picture

of recent developments in nucleonics and allied fields. It is planned to issue these articles in booklet form when the series is complete.

Jointly with the instruments and measurements committee of the Institute, a subcommittee on nucleonic instruments and controls was set up with Doctor G. W. Dunlap as chairman. This committee has held three meetings. It sponsored the session on nucleonics instruments referred to in the foregoing at the Pittsburgh meeting. It is planning additional sessions at the Washington and Spokane meetings.

Recently two additional subcommittees have been set up—one on nuclear physics with J. T. Wilson as chairman, and one on isotopic tracers with W. E. Barbour as chairman.

Another subcommittee on health safety is being planned jointly with the AIEE committee on therapeutics.

There is considerable activity not only in AIEE, but also in other professional organizations with regard to the development of a glossary of nuclear terms. This activity is being followed by the committee as it is desirable that such a glossary fill the needs in the various other technical fields, in addition to that of electrical engineering.

General Applications Group

COMMITTEE ON AIR TRANSPORTATION

The committee on air transportation held one meeting of the entire committee during the administrative year. This meeting was held in Dayton, Ohio, on September 26, 1947, following the Middle Eastern District meeting. At this meeting the Standards activities of the air transportation committee for the coming year were discussed and plans were made for technical sessions at future AIEE meetings.

The wide geographical spread of the aircraft industry has made active participation of interested groups in committee activities very difficult in the past. However, it is believed that this problem partially has been solved by the encouragement of the activities of air transportation divisions of the local Sections. In this way air transportation members may represent more effectively the majority opinion of the aviation industry when attending committee meetings.

Due to changes in personnel, the work of the committee and its subcommittees has been delayed to some extent. However, effort has been made to carry on the Standards program of the committee and to initiate new Standards to meet the requirements of the industry. The status of the committee's work is described under the heading of its several subcommittees as given in the following paragraphs.

Aircraft Electric Systems. This subcommittee has prepared the "Report on Aircraft Electric System Guide," AIEE 750, which was published in July 1947. The "System Guide" was issued with some sections incomplete with the aim of adding the unfinished section as soon as the material is available. At the present the subcommittees are co-operating in compiling information for the incomplete sections, which information will be correlated by the aircraft electric systems subcommittee and submitted to the Standards committee for inclusion in the "guide." In its present form the "System Guide" contains considerable valuable information which will be helpful to the designers and operators of aircraft electric systems. To increase the general acceptance of standard practices in aircraft electrical engineering it is desirable that the "System Guide" have a wider dissemination.

Aircraft Electric Rotating Machinery. The "Proposed Test Code for D-C Aircraft Machines," AIEE report 800, was issued March 1947 for one year's trial use. At the present a survey is being conducted to determine the extent of revisions and additions desirable in this proposed Standard, and to determine the recommendations of the air transportation committee to the Standards committee for its publication as an AIEE Standard.

This subcommittee at present is engaged in a project to formulate a new Standard on "Rating Standards of D-C Aircraft Generators." It is expected that a preliminary draft of this Standard will be ready for review by the air transportation committee by the end of 1948.

Aircraft Electric Control Protective Device and Cable. This subcommittee has been given the following assignment:

1. Prepare a test code for circuit interrupting devices.
2. Prepare test code for voltage regulators.

To date the first draft of "Proposed Test Code for Aircraft Circuit Interrupting Devices (12- and 24-volt d-c systems)" has been submitted to the subcommittee members for consideration and discussion. It is expected that this soon will be submitted to the Standards committee with recommendation that it be issued as a proposed test code for one year trial.

A working group has been appointed by the subcommittee to prepare a test code for d-c carbon pile voltage regulators. This working group has held three meetings and is scheduled to meet again in July 1948, at which time it is expected that a preliminary draft of the proposed test code will be presented for the consideration of and discussion by the group.

Basic Principles of Altitude Ratings. This subcommittee is preparing an AIEE Standard on the basic principles of altitude rating of electric machinery. The subcommittee has held three meetings and has compiled considerable information on environmental condition of altitude up to 50,000 feet. A survey is being conducted to determine the correlation of data obtained in flight with that obtained in altitude chambers. The survey also is to include the recommendation of users of altitude chambers concerning the use and limitation of chambers.

Joint Subcommittee (Air Transportation and Electric Machinery) on Carbon Brushes. This subcommittee is engaged in preparing an AIEE Standard for the testing of carbon brushes and brush material. Working groups have been formed of the subcommittee members to carry on the necessary investigations and to formulate the several phases of the standard test code necessary for the evaluation of carbon brush material and the performance of brushes on commutators and collector rings. It is expected that a preliminary draft of this Standard will be available by the end of 1948.

The air transportation committee is co-operating with the A2 committee of the Society of Automotive Engineers on problems of mutual interest. Liaison has been established with the National Aeronautical Standards Committee and with the Committee on Aviation and Airport Fire Protection, and it is expected that mutual benefit to all parties will result from the greater co-operative effort to produce working Standards which will be useful to the aviation industry.

Plans are being made for several technical sessions on air transportation at the Middle Eastern District meeting to be held in Washington, D. C., on October 5, 6, and 7, 1948. The response to the request for technical papers on aircraft electric subjects has been very gratifying. Effort is being made to stimulate increased preparation of technical papers and it is expected that technical sessions will be planned for more than one AIEE meeting during the next year.

COMMITTEE ON DOMESTIC AND COMMERCIAL APPLICATIONS

The committee on domestic and commercial applications, during the war years, was quite inactive and the present committee has been attempting to stimulate interest in the form of papers and discussions in the very broad field covered by the scope of this committee.

During the past year a very successful symposium on the heat pump was held in conjunction with the winter meeting of the Institute and work is under way now for a symposium on automatic protection of domestic equipment at the next winter meeting.

A paper on the application of inherent overheating protective devices for motors is scheduled for presentation at the summer meeting and one or two papers for District meetings are contemplated. While this is, perhaps, a small amount of activity when the tremendous advances in appliances of all kinds are considered, it is hoped it will be the beginning of a greater recognition among engineers generally of the real contribution that is being made by the engineers working on smaller equipment and publicized heretofore primarily through acceptance by the public rather than by any knowledge of their work by their fellow engineers in other lines.

Several subcommittees of this committee that have been completely inactive have been discontinued on the theory that contributions from an engineering standpoint are the only real justification for the existence of subcommittees. An alert and active main committee is contemplated instead.

COMMITTEE ON LAND TRANSPORTATION

Two well-attended meetings of the committee were held during the past year; one in June 1947 in Montreal and one during the winter meeting in January 1948 in Pittsburgh. The following activities were discussed and organized at these meetings.

Technical Meetings. Three transportation sessions were held at the winter meeting. A symposium on railroad electrification included papers on cost reduction of power

for electrification, conversion and transmission costs, overhead distribution costs, and electric locomotives with identical basic components. This session was unusually well attended and there was considerable interested discussion. A second session on heavy traction included papers on Great Northern Railroad motive power shunt capacitor installation on the New Haven, checking the integrity of high-speed train brakes, and speed responsive devices on Diesel-electric locomotives. The third session was on light traction and included papers on trolley coach distribution system, electric vehicles in city transit, new Chicago rapid transit cars, and a-c air conditioning for railroad passenger cars. These sessions were all very well attended. Two transportation papers are scheduled for the summer general meeting.

Subcommittee Activities. The subcommittee appointed to review AIEE Standard 16, "Standards for Electric Railway Control Apparatus," submitted an excellent report in June 1947. The committee voted to include in this Standard the electric portions of electropneumatic brakes. Representatives of two air brake companies now have been added to the subcommittee and a final report should be submitted in the near future.

The subcommittee engaged in gathering and tabulating heavy traction electrification data submitted questionnaires to the committee meeting in January and these questionnaires now are being duplicated and sent to the electrified railroads of the United States.

COMMITTEE ON MARINE TRANSPORTATION

Revisions of AIEE Standard 45 (Recommended Practice for Electric Installations on Shipboard), which is under the cognizance of this committee, have been completed.

The review of Standard 45 was completed in May 1947 and the results of the review were compiled, sorted to their appropriate heading, and referred to the committee's subcommittee chairmen for comparison with the existing Standard and further comments.

Subcommittee chairmen completed their work during the latter months of 1947 and submitted their comparisons and comments to the committee's editing subcommittee.

A meeting of the full committee was held February 27, 1948, at which meeting the work of the subcommittees was reviewed and with slight modifications, mutually agreed on, accepted.

A meeting of the committee's subcommittee chairmen was held April 15–16, 1948, with a representative of United States Coast Guard for the purpose of clarifying certain items of the proposed revisions.

Revision of Standard 45 in its final form has been prepared and submitted to the AIEE Standards committee for consideration.

COMMITTEE ON PRODUCTION AND APPLICATION OF LIGHT

The committee on the production and application of light arranged for a program for the Midwest general meeting in Chicago, Ill., on Tuesday, November 5, 1947. Technical papers were presented covering modern sources of infrared, visible, and ultraviolet radiation.

To encourage the planning of meetings on the subject of the production and application of light in various Sections, a letter was sent to all AIEE Section chairmen asking for a report on the number and type of such meetings which had been conducted within recent years, and offering the assistance of the committee in arranging such programs should they be desired. A number of the Sections requested assistance in arranging these programs, and such requests were referred to a member of the committee in the general area from which the request originated.

The remaining activities of the committee consisted of the formulation and continuation of certain subcommittee activities summarized in the following:

Subcommittee on Nomenclature of Electronic Lamps. This subcommittee was formulated several years ago at the request of the committee on electronics to assist in the preparation of definitions in the field of electronics by formulating definitions of lamps of this type.

Subcommittee on Preferred Voltage Characteristics of Electric Circuits for Lighting. A report from the previous chairman recommended that this particular subcommittee be discontinued. A copy of the report in which this recommendation was made is being circulated to various members of the committee to determine whether or not this recommendation will be followed.

Subcommittee on Infrared Radiation. A subcommittee to deal specifically with the subject of infrared radiation has been formulated and a program set up whereby it will work in close co-operation with the subcommittee on radiant heating of the technical committee on electric heating.

Subcommittee on Ultraviolet Radiation. A similar subcommittee was formulated to cover the field of the production and application of ultraviolet radiation.

The latter two subcommittees are working on specific assignments connected with the preparation of papers covering their specific fields.

Awards

INSTITUTE PRIZES

Five Institute prizes and ten District prizes were awarded for papers presented during the calendar year 1947, and for graduate and undergraduate student papers presented during the academic year ending June 30, 1947. A number of the papers were of a high order and the choice between leading papers in the several classes of Institute prizes was very close, so that six other papers received honorable mention.

Changes in prize awards for technical papers were announced in *ELECTRICAL ENGINEERING*, December 1947, pages 1248–9. Although it is too early to observe the effectiveness of these changes at the time of writing this report, 17 Branch prizes already have been awarded for the academic year ending July 30, 1948. This is a new prize established, one for each Branch, consisting of $10 cash plus an allowance of seven cents per mile one way for the winning representative to attend the District Branch competition.

CHARLES LEGEYT FORTESCUE FELLOWSHIP

This fellowship, which provides an allowance of $500 a year or more for graduate study in electrical engineering, was established as a memorial to Charles LeGeyt Fortescue in recognition of his valuable contributions to the electric power industry.

For the academic year 1948–49, a fellowship in the sum of $1,000 was awarded to James B. Woodford, Jr., a student at the Carnegie Institute of Technology, who will continue at that institution in graduate study.

COMMITTEE ON MEMBERS-FOR-LIFE FUND

The Members-For-Life fund committee held no meetings. By correspondence, it reviewed the use of the restricted fund and made recommendations to be embodied in report to President Hull, for board consideration at the summer general meeting.

EDISON MEDAL

The Edison Medal for 1947 was awarded to Doctor Joseph Slepian, associate director of the Westinghouse Research Laboratories, "For his theoretical and practical contributions to power systems through circuit analysis, arc control, and current interruption," and was presented on January 28, 1948, during the winter general meeting. The addresses given in connection with the presentation appear in *ELECTRICAL ENGINEERING* for March 1948, pages 258–64.

The medal may be awarded annually for meritorious achievement in electrical science, electrical engineering, or the electrical arts. Awards are made by a committee of 24 members of the Institute.

LAMME MEDAL

The Lamme Medal for 1947 was awarded to A. M. MacCutcheon, past president of the Institute, who retired, in 1946, from the position of vice-president in charge of engineering, Reliance Electric and Engineering Company, Cleveland, Ohio, "For his distinguished accomplishments in the development of motors for industrial needs, notably in the steel industry." The presentation will be made on June 23, 1948, during the summer general meeting in Mexico City.

Awards of the medal may be made annually by a committee of nine members of the Institute for meritorious achievement by a member of the AIEE in the development of electric apparatus or machinery.

HOOVER MEDAL

The Hoover Medal is awarded periodically to an engineer for distinguished public service by a board representing the American Society of Civil Engineers, American Institute of Mining and Metallurgical Engineers, American Society of Mechanical Engineers, and AIEE. No award was made for 1947.

JOHN FRITZ MEDAL

The John Fritz Medal may be awarded annually for notable scientific or industrial achievements, by a board of award composed of representatives of the ASCE, AIME, ASME, and AIEE. The 1948 medal was awarded to Doctor Theodor von Kármán as a "creative leader, stimulating teacher, and wise counselor in engineering and physical research in the fields of the aeronautical and structural sciences, for his many applications of mathematical and physical theory to the sound solution of engineering problems."

WASHINGTON AWARD

The Washington Award for 1948 was made to Senator Ralph E. Flanders of Vermont, who is president of the Jones and Lamson Machine Company, Springfield, Vt. The award is made annually to an outstanding engineer, a citizen or resident of the United States, who ably has served

human needs, and is administered by a commission representing the Western Society of Engineers, ASCE, AIME, ASME, and AIEE.

ALFRED NOBLE PRIZE

This prize was established in 1929 to perpetuate the name and achievements of Alfred Noble, past president of the ASCE and the Western Society of Engineers. It may be made to a member of any of the co-operating societies, ASCE, AIME, ASME, AIEE, or WSE, for a technical paper of particular merit accepted by the publication committee of any of these societies, provided the author is not over 30 years of age at the time of such acceptance.

Joint Activities

UNITED ENGINEERING TRUSTEES, INC.

This organization manages property and funds held jointly by the four Founder Societies, including the Engineering Societies Building, the Engineering Societies Library, and the endowment funds of the Engineering Foundation. It also acts as treasurer for the Engineers' Council for Professional Development.

An abstract of the annual report of UET for the year ended September 30, 1947, appears in *ELECTRICAL ENGINEERING*, February 1948, page 209.

ENGINEERING FOUNDATION

The Engineering Foundation, a department of United Engineering Trustees, was established in 1914 as a joint agency of the Founder Societies for "the furtherance of research in science and engineering."

As part of its program, the foundation supported 13 research projects during the year 1946–47. For the current year it is continuing the maintenance of nine of these projects, and has added eight new ones.

An abstract of the annual report for the year ended September 30, 1947, appears in *ELECTRICAL ENGINEERING*, February 1948, pages 210–11.

ENGINEERING SOCIETIES LIBRARY

The Engineering Societies Library, formed by combining the separate libraries of the ASCE, AIME, ASME, and AIEE, is conducted as a free public reference library.

Total resources of the library presently include 164,051 volumes, 10,316 maps, and 4,943 searches. The library also renders special services such as translations, photoprints, bibliographies, and book loans by mail.

An abstract of the annual report for the year ended September 30, 1947, appears in *ELECTRICAL ENGINEERING*, February 1948, pages 209–10.

ENGINEERS' COUNCIL FOR PROFESSIONAL DEVELOPMENT

The principal activities of ECPD include "programs for the guidance of young persons thinking of entering the engineering field, the accrediting of curricula of engineering schools, encouragement and assistance to individuals in their engineering and cultural studies during several years following graduation, and the development of criteria for indicating the attainment of the status of an engineer." The council represents the national societies of chemical, civil, electrical, mechanical, and mining and metallurgical engineers. The Engineering Institute of Canada, the American Society for Engineering Education, and the National Council of State Boards of Engineering Examiners.

A report of ECPD's activities during the year 1946–47 is included in the annual report of the Engineering Foundation (*EE, Feb '48, p 211*).

ENGINEERING SOCIETIES PERSONNEL SERVICE, INC.

Operating as an incorporated nonprofit organization, the Engineering Societies Personnel Service, Inc., assists members of the Founder Societies desiring to secure new positions and employers searching for engineers. Nonmembers may receive such assistance when positions available cannot be filled by members.

Offices are operated in New York, N.Y.; Detroit, Mich.; Chicago, Ill.; San Francisco, Calif.; with the co-operation of the Engineering Society of Detroit in that city, the Western Society of Engineers in Chicago, and the Engineers Club of San Francisco in that city.

ENGINEERS JOINT COUNCIL

This council, formerly known as the joint conference committee, is composed of the presidents, immediate past presidents, and secretaries of the Founder Societies and the AIChE. Its functions are to consider matters of interest to the societies and to make recommendations to their governing bodies.

REPRESENTATIVES

A complete list of about 40 joint bodies upon which the Institute is represented appears in the Year Book and in the October issue of *ELECTRICAL ENGINEERING* each year.

Appreciation

The board of directors acknowledges with appreciation and thanks the splendid co-operation received from Institute committees, District, Section, and Branch officers, and the membership.

Respectfully submitted for the board of directors.

H. H. HENLINE
Secretary

Official group of AIEE national officers and local representatives, acting as a special guard of honor, placed a memorial wreath at the Perpetual Flame in the base of the Monument to the Heroes of the Mexican Independence, June 22, 1948, during the 1948 AIEE summer general meeting. Left to right: Director J. M. Flanigen of Atlanta, Ga.; Vice-President E. W. Davis of Cambridge, Mass.; Director J. F. Fairman of New York City; Vice-president J. H. Berry of Norfolk, Va.; Vice-President C. F. Terrell of Seattle, Wash.; Past-President J. Elmer Housley of Alcoa, Tenn.; Jorge Rivera S. of the hospitality committee; Hector Martinez D'Meza, vice president of the summer general meeting committee; Secretary H. H. Henline of New York; Oscar R. Enriquez of Mexico City, president of the summer general meeting committee; AIEE President Blake D. Hull of Dallas, Texas; Manuel M. de Lascurain of Mexico City, member of the executive group of the summer general meeting committee; AIEE President-Elect Everett S. Lee of Schenectady, N. Y.; Director R. T. Henry of Buffalo, N. Y.; Director D. A. Quarles of New York, N. Y.; Vice-President-Elect Victor Siegfried of Worcester, Mass.; Vice-President D. G. Geiger of Toronto, Canada; Director E. P. Yerkes of Philadelphia, Pa.; Vice-President R. F. Danner of Oklahoma City, Okla.; Director Walter C. Smith of Palo Alto, Calif.

HASKINS & SELLS
CERTIFIED PUBLIC ACCOUNTANTS

1 EAST 44TH STREET
NEW YORK 17

May 19, 1948

American Institute of Electrical Engineers,
33 West 39th Street, New York.

Dear Sirs:

We have examined the balance sheet of the American Institute of Electrical Engineers, and schedule of securities owned, as of April 30, 1948, and the related statements of cash receipts and disbursements of operating and restricted funds for the year ended that date. Our examination was made in accordance with generally accepted auditing standards and included such tests of the accounting records and such other auditing procedures as we considered necessary in the circumstances.

In our opinion, the accompanying balance sheet, schedule of securities owned, and statements of cash receipts and disbursements, respectively, present fairly the financial condition of, and securities owned by, the Institute as of April 30, 1948, and its recorded cash receipts and cash disbursements for the year ended that date, in conformity with generally accepted accounting principles applied on a basis consistent with that of the preceding year.

Yours truly,

(*Signed*) HASKINS & SELLS

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Balance Sheet, April 30, 1948

Exhibit A

ASSETS

Property Fund Assets:		
One-fourth interest in physical properties of United Engineering Trustees, Inc.:		
Land, buildings, and equipment (less depreciation and renewal reserve)	$342,957.02	
Funded depreciation and renewal reserve	155,491.46	
Total	$498,448.48	
Equipment:		
Library (volumes and fixtures)—estimated value	36,366.37	
Office furniture and fixtures (less reserve for depreciation, $30,708.19)	15,019.07	
Works of art, etc.	3,001.35	
Cash (no change during year)	612.91	
Total property fund assets		$ 553,448.18
Restricted Fund Assets:		
Securities—at cost, less reserve, $1,788.15 (quoted market value, $555,516.78)—Schedule 1	$534,223.30	
Cash (Exhibit C)	39,398.08	
Accrued interest receivable	125.40	
Total restricted fund assets		573,746.78
Operating Fund Assets:		
Cash (not including $2,031.98 for Federal taxes withheld from employees)—(Exhibit *B*)	$22,394.58	
Accounts receivable:		
Members—for dues (less reserve, $4,500.00)	11,824.95	
Advertisers	1,449.25	
Miscellaneous	4,356.05	
Accrued interest receivable	8,450.55	
Inventories:		
TRANSACTIONS, etc.	1,216.00	
"Electrical Definitions"	1,409.40	
Work in process (May issue of *ELECTRICAL ENGINEERING*, etc.)	14,271.27	
Text and cover paper	17,592.46	
Badges	7,123.35	
Total operating fund assets		90,087.86
Total		$1,217,282.82

LIABILITIES

Property Fund Reserve		$ 553,448.18
Restricted Fund Reserves:		
Reserve capital fund	$544,847.61	
Life membership fund	8,636.75	
Member-for-Life fund	8,416.86	
International Electrical Congress of St. Louis library fund	6,400.11	
Lamme Medal fund	4,430.44	
Mailloux fund	1,015.01	
Total restricted fund reserves		573,746.78
Operating Fund Reserves, Liabilities, etc.:		
Accounts payable	$ 21,701.08	
Deferred income:		
Dues received in advance	3,390.00	
Entrance fees and dues advanced by applicants for membership	1,833.30	
Subscriptions to publications received in advance	18,998.34	
Miscellaneous (including unallocated receipts)	1,306.14	
Operating fund reserves	42,859.00	
Total operating fund reserves, liabilities, etc.		90,087.86
Total		$1,217,282.82

Statement of Cash Receipts and Disbursements of Operating Fund for the Year Ended April 30, 1948

Exhibit B

Cash on Deposit with The National City Bank of New York, May 1, 1947 (not including $1,664.75 for Federal taxes withheld from employees)		$ 6,883.37
Receipts:		
Dues (including $154,866.00 allocated to *ELECTRICAL ENGINEERING* subscriptions)	$332,459.02	
Advertising	128,817.86

W. L. Everitt — E. M. Strong
H. E. Hartig — J. G. Tarboux
T. N. Linville — G. F. Tracy
E. A. Loew — C. E. Tucker
A. H. Lovell — C. E. Tultes
K. B. McEachron, Jr. — E. A. Walker
T. G. McFarland — R. W. Warner
H. N. Muller, Jr. — S. Reid Warren

Lamme Medal

N. S. Hibshman, *chairman* — T. G. LeClair — A. C. Monteith (*Terms expire July 31, 1949*)
F. E. Harrell — D. A. Quarles — J. B. Thomas (*Terms expire July 31, 1950*)
J. H. Berry — T. H. Morgan — L. A. Umansky (*Terms expire July 31, 1951*)

Management

W. L. Cisler, *chairman*, Detroit Edison Company, 2000 Second Avenue, Detroit 26, Mich.
P. L. Alger — Lee H. Hill
K. P. Applegate — A. C. Monteith
C. J. Beller — E. L. Moreland
R. D. Bennett — H. A. Peterson
H. K. Breckenridge — D. A. Quarles
F. W. Bush — F. M. Roberts
E. E. Hill — O. Van Rye

Prizes, Award of Institute

H. M. Turner, *chairman*, Yale University, New Haven, Conn.
H. C. Coleman — J. J. Orr
H. L. Davis, Jr. — J. J. Pilliod
B. M. Jones — F. M. Sebast
W. C. Kalb — M. J. Steinberg
T. G. LeClair — J. C. Strasbourger
H. N. Muller, Jr. — C. G. Suits
J. D. Tebo

Registration of Engineers

L. E. Hobson, *chairman*, Stanford Research Institute, Stanford University, Stanford, Calif.
J. H. Bancker — R. E. Kistler
E. O. Campbell — K. B. McEachron
H. S. Dixon — R. E. Muchlig
J. H. Foote — J. G. Patterson
N. L. Freeman — W. W. Perry
L. A. Griffith — Elgin B. Robertson
J. D. Guillemette — L. M. Robertson
F. W. L. Hill — R. W. Sorensen
Harry B. Joyce — R. G. Warner

Student Branches

H. N. Muller, Jr., *chairman*, Westinghouse Electric Corporation, East Pittsburgh, Pa.
Sterling Beckwith — F. O. McMillan
J. F. Calvert — W. H. Pickering
P. L. Hoover — R. G. Porter
J. H. Kuhlmann — L. T. Rader
J. D. McCrumm — R. W. Warner
B. S. Willis

Ex-officio
Student Branch counselors

Technical Committees

Power Group

Power Co-ordinating Committee

M. J. Steinberg, *chairman*, Consolidated Edison Company of New York, Inc., 4 Irving Place, New York, N. Y.
H. W. Collins
R. T. Henry
A. J. Krupy
W. J. McLaughlan
Frank Thornton, Jr.

Ex-officio
Chairmen of the 11 following technical committees in the power group

Carrier Current

L. F. Kennedy, *chairman*, General Electric Company, central station engineering divisions, 1 River Road, Schenectady 5, N. Y.

(*Continued in next column*)

S. C. Bartlett — S. Lubin
W. H. Blankmeyer — L. E. Ludekens
C. W. Boadway — D. M. MacGregor
J. M. Dunham — T. W. MacLean
L. G. Eaton — R. H. Miller
R. C. Ericson — R. E. Neidig
L. F. Ferri — F. M. Rives
W. J. Googe — Merle Robison
K. E. Hapgood — Trueman T. Smith
E. W. Kenefake — Oliver A. Starcke
S. C. Leyland — T. D. Talmage
Mead Warren, Jr.

CARRIER CURRENT SUBCOMMITTEES

1. Project—Preparation of a General Interest Paper on Carrier Current

Scope: This paper is to give a historical review of the carrier developments and outline the place the carrier has in present-day system operating practices.

J. D. Booth, *chairman* — L. F. Kennedy
S. C. Bartlett

2. Project Committee Report on Application Guidance for Carrier Current

D. M. MacGregor, *chairman* — T. D. Talmage
C. W. Boadway

3. Working Group to Prepare Suggested Methods of Measurement

Scope: Establishment of methods of measurements in the carrier field.

E. W. Kenefake, *chairman* — C. W. Boadway
S. C. Bartlett — M. H. Wood

4. Working Group on High-Frequency Characteristics of Power Equipment

S. C. Leyland, *chairman* — T. A. Cramer

5. Working Group for Data on Carrier-Current Characteristics of Transmission Lines and Systems

Scope: Power system measurements at carrier frequency dealing primarily with transmission lines and substations.

R. C. Ericson, *chairman* — W. J. Googe
W. H. Blankmeyer — L. E. Ludekens
T. D. Talmage

6. Working Group on Standard Terminology for Carrier Current

S. C. Leyland, *chairman*

7. Working Group on Coupling Capacitors and Traps for Rural Line Carrier Telephone

S. C. Bartlett, *chairman*

8. Working Group on Use of Microwave Equipment for Relaying Telemetering and Supervisory Control

S. C. Leyland, *chairman*

9. Working Group on Operating Experience with Carrier Current Relaying Channels

O. A. Starcke, *chairman*

Insulated Conductors

L. F. Hickernell, *chairman*, Anaconda Wire and Cable Company, Hastings-on-Hudson 6, N. Y.
G. W. Acock — Glen T. Koger
C. F. Avila — L. I. Komives
H. G. Barnett — M. J. Lowenberg
C. E. Baugh — C. G. Mansfield
A. Bodicky — R. E. Morse
A. S. Brookes — E. F. Nuetzel
T. J. Brosnan — W. T. Peirce
W. R. Bullard — R. S. Peterson
H. W. Clark — A. D. Pettee
M. T. Crawford — H. S. Phelps
Alan S. Dana — R. A. Schatzel
E. W. Davis — G. B. Shanklin
W. A. Del Mar — V. A. Sheals
C. D. Eash — H. D. Short
D. M. Farnham — F. V. Smith
G. H. Fiedler — L. G. Smith
L. E. Fogg — G. M. L. Sommerman
J. H. Foote — E. G. Sturdevant
M. W. Ghen — Gordon Thompson
H. Halperin — C. W. White
C. T. Hatcher — R. J. Wiseman
T. G. Hieronymus — K. S. Wyatt
R. A. Hopkins — C. W. Zimmerer

INSULATED CONDUCTORS SUBCOMMITTEES

1. Administration Subcommittee

Scope: The activities of this subcommittee include subcommittee organization and scopes, co-ordination of subcommittee activities, program planning, and selection of papers for national meetings.

Main Committee Officers:
L. F. Hickernell, *chairman* — C. T. Hatcher, *secretary*
H. Halperin, *vice-chairman* — R. J. Wiseman

Subcommittee Chairmen:
A. S. Brookes — G. T. Koger
W. A. Del Mar — L. I. Komives
G. H. Fiedler — W. T. Peirce
J. H. Foote — R. S. Peterson
M. W. Ghen — G. M. L. Sommerman
Gordon Thompson

2. Standards and Publications Subcommittee

A. S. Brookes, *chairman* — J. H. Foote
A. P. S. Bellis — V. A. Sheals
L. E. Fogg — C. W. Zimmerer

Projects:
(2-1). Standard number 30 (1944)—revision
(2-2). Insulated Conductor Reference Book

3. Cable Characteristics Subcommittee

W. A. Del Mar, *chairman* — M. H. McGrath
H. Halperin — J. H. Neher
C. T. Hatcher — G. B. Shanklin
C. G. Mansfield — R. J. Wiseman — F. V. Smith

Projects:
(3-1). Current-carrying capacity of buried cables
(3-2). Zero-sequence impedance of cables
(3-3). A-c resistance of cables in conduit (paper)
(3-4). Reactance of cables in conduit (paper)
(3-5). Use of reduced-scale models for the solution of cable problems
(3-6). Hydraulic aspect of oil-filled pipe cables
(3-7). Movement of buried cable

4. Conductors Subcommittee

H. Foote, *chairman*

Projects:
(4-1). Determination of conductor resistivity
(4-2). Definition of terms relating to conductors
(4-3). *NBS* circular number 31—revision

5. Insulations Subcommittee

G. M. L. Sommerman, *chairman* — E. W. Greenfield
J. C. Balsbaugh — J. D. Piper
C. E. Betzer — R. A. Schatzel
F. M. Clark — A. J. Warner
A. S. Dana — K. S. Wyatt

Projects:
(5-1). Properties of synthetic rubber and plastics

6. Sheaths and Coverings Subcommittee

G. H. Fiedler, *chairman* — A. D. Pettee
C. E. Betzer — H. S. Phelps
A. S. Brookes — V. A. Sheals
F. E. Kulman — G. W. Zink

Projects:
(6-1). Properties of lead and lead alloy sheathing
(6-2). Properties of nonmetallic sheaths
(6-3). Protective covering for lead sheathing
(6-4). Evaluation of simulated service tests on lead sheathing

7. Cable Supply Systems Subcommittee

L. I. Komives, *chairman* — C. T. Hatcher
G. F. Avila — A. D. Pettee
H. G. Barnett — C. S. Schifreen
T. J. Brosnan — G. B. Shanklin
W. R. Bullard — H. D. Short
H. W. Clark — C. W. White
D. M. Farnham — R. J. Wiseman
H. Halperin — K. S. Wyatt

Projects:
(7-3). 69-kv cable installations at Philadelphia (paper)
(7-5). 69-kv cable installation at Milwaukee (paper)
(7-6). Nonmetallic sheathed cable in ducts for primary distribution
(7-7). Nonmetallic sheathed cable in ducts for secondary distribution
(7-8). Buried cable for distribution systems
(7-9). Aerial cable for distribution systems
(7-10). 69-kv medium-pressure gas-filled cable installation at Washington, D. C.
(7-11). Low-pressure gas-filled cable installations
(7-12). Paper cable with reduced insulation, short lays, soft binders, and so forth
(7-13). Economics of various types of extra-high-voltage cable systems
(7-14). Low versus high-viscosity oil for gas-pressure cable

8. Utilization Wiring Systems Subcommittee

G. T. Koger, *chairman* — L. C. Peterman
E. L. Bailey — Kennard Pinder
H. G. Barnett — S. J. Rosch
Allan Coggeshall — R. A. Schatzel
C. A. Finkel — E. G. Sturdevant
M. G. Houghton — C. V. Waddington
M. J. Lowenberg — C. W. Zimmerer
J. B. MacLean — G. W. Zink

Projects:

(8-1). National Electric Code—Problems affecting its application

(8-2). Wiring systems for corrosive and hazardous locations

(8-3). Metallic versus nonmetallic wiring

(8-4). Insulated aluminum conductors for utilization voltages

(8-5). The case for the bare neutral

(8-6). Conduit as a return conductor

9. Special Purpose Cables Subcommittee

W. T. Peirce, *chairman* — R. A. Hopkins
G. W. Acock — G. H. Landis
J. F. Atkinson — M. J. Lowenberg
M. T. Crawford — H. S. Moore
E. W. Davis — F. V. Smith
S. F. French — Myron Zucker — W. N. Zippler

Projects:

(9-1). Standard number 45—sections 18, 19, 20 (1945) —revision

(9-2). American versus foreign shipboard cable practice

(9-3). Mining cable

(9-4). Vertical-riser cable

(9-5). Generator lead cable

10. Accessories Subcommittee

M. W. Ghen, *chairman* — H. E. Martin
C. Christianson — R. E. Morse
C. D. Eash — J. H. Nicholas
T. G. Hieronymus — E. F. Nuezel
J. E. Johnson — F. P. West
L. Wetherill

Projects:

(10-1). Standard number 48 on cable potheads (1948) —discussion

(10-2). Termination of nonmetallic sheathed cables

(10-3). Development and technique of soldered porcelain potheads

(10-4). Interchangeability of potheads

(10-5). Molded joints for polyethylene-insulated coaxial cable

(10-6). Standard on cable limiters

(10-7). Effect of external bushing contamination on flashover value of potheads

(10-8). Fundamental design characteristics of potheads

(10-9). Aerial-cable accessories

11. Structures Subcommittee

R. S. Peterson, *chairman* — C. D. Eash
C. E. Baugh — G. H. Fiedler
Andrew Bodicky — M. W. Ghen
T. J. Brosnan — C. G. Mansfield
H. W. Clark — L. G. Smith
H. L. Davis, Jr. — F. P. West

Projects:

(11-1). Conduits

(11-2). Gases in underground structures

(11-3). Transformer manhole and vault design and ventilation

(11-4). Manhole construction

(11-5). Supports for aerial cable

(11-6). Supports for bridge cable

(11-7). Under river crossings

(11-8). Submarine cables and methods of support

(11-9). Cable installations in tunnels

12. Tests and Measurements Subcommittee

Gordon Thompson, *chairman* — E. S. Halfmann
J. C. Balsbaugh — F. K. Harris
A. L. Brownlee — J. C. Parker
R. W. Chadbourn — H. D. Short
A. S. Dana — G. M. L. Sommerman
E. W. Davis — E. R. Thomas
W. A. Del Mar — R. J. Wiseman
E. W. Greenfield — C. W. Zimmerer

Projects:

(12-1). Test code for insulated conductors

(12-2). Equivalent 1-hour life for oil-filled and gas-filled cable

(12-3). High-frequency measurements

(12-4). A-c resistance and reactance measurements

(12-5). Impulse strength testing

(12-6). Practice in testing of installed cables

(12-7). Determination of tensile strength of lead sheathing

Power Generation

A. H. Frampton, *chairman*, English Electric Company of Canada Ltd., St. Catherines, Ont., Canada

H. A. Adler — W. R. Johnson
R. E. Appleyard — L. A. Kilgore
J. E. Barkle — A. J. Krupy
S. Beckwith — F. L. Lawton
J. A. Brooks — W. J. Lyman
G. Calabrese — J. T. Madill

(*continued in next column*)

A. D. Caskey — A. P. Maness
S. M. Denton — T. H. Mawson
E. F. Dissmeyer — J. B. McClure
Alex. Dovjikov — G. H. McDaniel
J. M. Drabelle — D. R. Pattison
J. Finlaw — W. S. Peterson
C. B. Fontaine — A. L. Pollard
C. A. Harrington — F. L. Reinmann
H. R. Harris — B. G. A. Skrotzki
A. P. Hayward — G. M. Tatum
B. V. Hoard — C. W. Watchorn
E. L. Hough — G. R. Woodman

POWER GENERATION SUBCOMMITTEES

1. Prime Movers Subcommittee

Scope: To study, review design, installation practices, and other features of all types of prime movers and their associated equipment (except hydraulic units) as related to electric power generation. To sponsor specifications, Standards, and technical sessions, the latter to be devoted principally to new developments or review of existing practices. To co-operate with other committees of organizations such as American Society of Mechanical Engineers and Edison Electric Institute.

B. G. A. Skrotzki, *chairman* — J. A. Brooks
H. A. Adler — J. Finlaw
S. Beckwith — H. R. Harris

2. Speed Governing Subcommittee

Scope: To study, review design, installation practices, and other features of all types of prime-mover governing systems, including hydroelectric. To sponsor specifications, Standards, and technical sessions and co-operate with other committees of the AIEE and other societies.

J. B. McClure, *chairman* — A. P. Hayward
C. P. Almon, Jr. — T. H. Mawson
R. E. Appleyard — G. H. McDaniel
R. M. Beville — F. L. Reinmann

3. Excitation Systems Subcommittee

Scope: Similar functions as for the speed-governing subcommittee in the field of generating-station excitation systems.

A. J. Krupy, *chairman* — A. Dovjikov
J. E. Barkle, Jr. — C. B. Fontaine, Jr.
E. F. Dissmeyer — L. A. Kilgore
J. B. McClure

4. Station Design Subcommittee

Scope: To review designs and installation practices in electric generating stations considered as a unit. To sponsor technical sessions covering new or improved practices. To analyze trends and designs and present general interest material of future possibilities. This subcommittee will not cover hydroelectric stations

A. D. Caskey, *chairman* — E. L. Hough
J. M. Drabelle — W. R. Johnson
C. A. Harrington — D. R. Pattison

5. Hydroelectric Systems Subcommittee

Scope: Combining the scope, for hydroelectric station only, of the prime movers and station design subcommittees.

W. S. Peterson, *chairman* — J. T. Madill
S. M. Denton — A. P. Maness
B. V. Hoard — A. L. Pollard
F. L. Lawton — G. R. Woodman
L. B. Stirling

6. Pacific Coast Subcommittee

Scope: To foster closer co-operation with the western members in all projects undertaken by the main committee. To provide direct contact in the planning of Pacific Coast technical meetings.

A. Dovjikov, *chairman* — W. R. Johnson
S. M. Denton — W. S. Peterson
B. V. Hoard — A. L. Pollard
G. R. Woodman

Protective Devices

G. B. Dodds, *chairman*, Duquesne Light Company, 435 Sixth Avenue, Pittsburgh 19, Pa.

V. J. Cisma — W. A. Lewis, Jr.
J. E. Clem — F. R. Longley
L. M. Connors — C. Lowerison
H. A. Cornelius — T. H. Mawson
F. M. Defandorf — C. McLean
R. H. Earle — E. G. Norell
W. W. Eberhardt — A. M. Opsahl
G. W. Gerell — W. J. Rudge
E. M. Hunter — W. E. Rushlow
T. I. Eldridge — O. L. Sidenfaden
P. A. Jeanne — W. T. Smith
Alva A. Johnson — H. R. Stewart
J. H. Kinghorn — J. M. Towner
E. W. Knapp — S. S. Watkins
W. E. Knouse — E. H. Yonkers

PROTECTIVE DEVICES SUBCOMMITTEES

1. Lightning Protective Devices Subcommittee

H. R. Stewart, *chairman* — H. W. Hartzell
E. H. Yonkers, *secretary* — T. W. Mawson
H. A. Cornelius — J. R. McFarlin
F. M. Defandorf — W. A. McMorris
R. H. Earle — A. M. Opsahl
Milan Getting — W. E. Rushlow
I. W. Gross — A. H. Schirmer
E. H. Grosser — J. M. Towner
E. R. Whitehead

Project 1: Application guide of methods for lightning protection of substations.

H. A. Cornelius, *chairman* — S. B. Howard
E. H. Grosser — E. L. Jarrett
H. W. Hartzell — R. H. Mertz
A. M. Opsahl

Project 4: Lightning protection for unit substations.

E. R. Whitehead, *chairman* — E. M. Hunter
H. W. Hartzell — A. A. Johnson
J. M. Towner

Project 5: Revise and combine AIEE Standards 24, 28 and 47.

F. M. Defandorf, *chairman* — W. A. McMorris
R. H. Earle — A. M. Opsahl
I. W. Gross — W. E. Rushlow
E. H. Grosser — A. H. Schirmer
J. R. McFarlin — J. M. Towner
E. H. Yonkers

Project 6: Performance characteristics of station type arresters.

W. A. McMorris, *chairman*

Project 7: Performance characteristics of valve type distribution arresters.

J. R. McFarlin, *chairman* — T. I. Eldridge
R. H. Earle — W. A. McMorris
A. M. Opsahl

Project 8: Performance characteristics of 20 to 73 kv line type arresters.

R. H. Earle, *chairman*

Project 9: Joint working group (with general systems subcommittee of transmission and distribution committee) on recovery voltage characteristics of distribution systems.

R. L. Witzke, *chairman* — L. M. Olmstead
I. B. Johnson — M. A. Polster
W. E. Rushlow

Project 10: Performance characteristics of line expulsion arresters.

A. M. Opsahl, *chairman*

Project 11: Combined performance characteristics of lightning protective devices.

E. H. Grosser, *chairman* — Milan Getting
R. H. Earle — W. A. McMorris
J. R. McFarlin — A. M. Opsahl

Project 12: Status of rod gap characteristics.

Milan Getting, *chairman*

2. Fault Limiting Devices Subcommittee

A. A. Johnson, *chairman* — E. W. Knapp
J. E. Clem — W. A. Lewis
W. W. Eberhardt — F. R. Longley
E. T. B. Gross — W. E. Marter
H. W. Hartzell — E. G. Norell
E. M. Hunter — O. L. Sidenfaden
P. A. Jeanne — W. T. Smith

Project 1: Application guide on methods of grounding transmission systems.

E. M. Hunter, *chairman* — A. A. Johnson
H. W. Hartzell — R. E. Neidig

Project 2: Application guide on methods of grounding generator systems.

A. A. Johnson, *chairman* — W. E. Marter
E. M. Hunter — E. G. Norell
D. M. MacGregor — W. T. Smith

Project 3: Bibliography of literature on grounding devices.

E. T. B. Gross, *chairman* — P. A. Jeanne — W. A. Lewis

Project 4: Field survey of and application problems associated with ground fault neutralizers.

J. E. Clem, *chairman* — S. S. Cook
H. H. Brown — N. E. Dillon
B. H. Clingerman — W. D. Hardaway
R. E. Neidig

Project 5: Power system fault limitation.

F. R. Longley, *chairman* — L. B. LeVeaconte
J. O. R. Coleman — H. F. Lindemuth
F. H. Kierstead — E. L. Michelson
L. E. Sauer

Relays

W. R. Brownlee, *chairman*, The Commonwealth and Southern Corporation, Jackson, Mich.

R. J. Cooper	S. C. Leyland
R. E. Cordray	H. F. Lindemuth
G. E. Dana	J. R. Linders
G. B. Dodds	C. Lowerison
F. S. Fehr	W. E. Marter
L. F. Ferri	A. J. McConnell
L. L. Fountain	E. L. Michelson
S. Goldsmith	W. A. Morgan
E. T. B. Gross	C. E. Parks
T. R. Halman	H. R. Paxson
E. L. Harder	F. C. Poage
V. J. Hayes	E. G. Ratz
B. C. Hicks	K. N. Reardon
J. H. Kinghorn	H. P. Sleeper
R. A. Larner	W. K. Sonnemann
W. A. Lewis, Jr.	G. S. Steeb
E. C. Wentz	

RELAYS SUBCOMMITTEES

1. Project Committee on Bibliography of Relay Literature

E. T. B. Gross, *chairman*	C. E. Parks
S. Goldsmith	C. L. Smith

2. Project Committee on Generator Protection

H. R. Paxson, *chairman*	W. E. Marter
L. L. Draper	J. B. McClure
B. C. Hicks	A. J. McConnell
S. C. Leyland	C. E. Parks
H. F. Lindemuth	F. C. Poage
C. L. Smith	

3. Project Committee on Co-ordination of Construction and Protection of Distribution Circuits (Joint with Distribution Subcommittee and Edison Electric Institute)

G. B. Dodds, *AIEE sponsor* C. J. Beller, *SEI sponsor*

Relay Committee Appointees:	*Distribution Subcommittee Appointees:*	*EEI*
H. W. Haberl	R. O. Askey	G. H. Fiedler
C. L. Headley	T. J. Brosnan	W. McLean
C. Lowerison	W. B. Fisk	E. W. Knapp
C. E. Parks	A. L. Malmstrom	
H. P. Sleeper	H. F. Outman	
C. L. Smith	J. S. Parsons	
	R. F. Quinn	

4. Project Committee on Revision of Standards for Power Relays

S. C. Leyland, *chairman*	L. L. Fountain
R. E. Cordray	W. A. Lewis
V. L. Cox	E. L. Michelson

5. Project Committee on Sensitive Ground Protection

E. T. B. Gross, *chairman*	P. A. Jeanne
C. J. Berghs	C. Lowerison
R. J. Cooper	W. K. Sonnemann
T. R. Halman	A. R. van C. Warrington

6. Project Committee on Transmission Line Protection

E. L. Harder, *chairman*	W. E. Marter
L. J. Audlin	A. J. McConnell
W. R. Brownlee	M. S. Merritt
B. C. Hicks	E. L. Michelson
J. H. Kinghorn	C. E. Parks
W. A. Lewis	K. N. Reardon

7. Project Committee on Electronic Relay Applications

A. J. McConnell, *chairman*	E. L. Harder
J. E. Barkle	J. H. Kinghorn
R. J. Cooper	D. M. McGregor
F. S. Fehr	E. L. Michelson
E. G. Ratz	

8. Project Committee on Insulation Levels of Relay and Control Circuit

E. L. Michelson, *chairman*	T. R. Halman
R. E. Cordray	V. J. Hayes
S. Goldsmith	W. K. Sonnemann

9. Project Committee on Relaying of Interconnections Between Industrial and Utility Generating Systems

K. N. Reardon, *chairman*	F. S. Fehr
J. E. Barkle	T. R. Halman
G. E. Dana	J. R. Linders

10. Projection Committee on Relay Protection for Stations Without High-Voltage Switching

E. L. Michelson, *chairman*	V. J. Hayes
L. F. Ferri	R. A. Larner
L. L. Fountain	K. N. Reardon

11. Proposed Future Projects:

(*a*). Capacitance potential device transient performance as influencing relay operation.

(*b*). Review of bus protection methods and performance.

(*c*). Relay protection of circuits following sustained interruptions.

(*d*). A-c and low-voltage d-c tripping methods (joint).

(*e*). Relay test methods.

(*f*). Switching schemes influencing relay protection.

(*g*). Ultrahigh-frequency radio protective relay applications.

(*h*). Design and protection of pilot-wire channels.

(*i*). Uniform records of relay performance.

Rotating Machinery

C. E. Kilbourne, *chairman*, General Electric Company, turbine division, 1 River Road, Schenectady 5, N. Y.

J. E. Allen	A. A. Kroneberg
G. R. Anderson	T. M. Linville
W. R. Appleman	T. C. Lloyd
E. L. Bailey	M. R. Lory
S. Beckwith	C. Lynn
A. G. Conrad	G. W. McIver, Jr.
J. DeKiep	R. C. Moore
L. O. Dorfman	J. G. Noest
E. E. Dreese	E. I. Pollard
J. L. Fuller	C. P. Potter
J. S. Gault	F. C. Rushing
C. B. Hathaway	M. L. Schmidt
V. P. Hessler	R. V. Shepherd
L. E. Hildebrand	J. F. Sellers
T. A. Hopkins	H. R. Sills
W. R. Hough	T. W. Trice
J. W. Jones	P. H. Trickey
M. F. Kent	C. G. Veinott
C. Kingsley, Jr.	R. W. Wieseman

ROTATING MACHINERY SUBCOMMITTEES

1. Administrative Subcommittee

C. E. Kilbourne, *chairman*	E. I. Pollard
W. R. Hough	F. C. Rushing
T. M. Linville	M. L. Schmidt
J. L. Fuller	R. W. Wieseman

2. Synchronous Machinery Subcommittee

E. I. Pollard, *chairman*	E. L. Harder
Sterling Beckwith	R. A. Hopkins
J. F. Calvert	L. F. Hunt
S. B. Crary	J. W. Jones
J. DeKiep	C. E. Kilbourne
L. O. Dorfman	G. W. McIver
A. M. Goodison, Jr.	W. P. Monroe
J. G. Noest	

3. Induction Machinery Subcommittee

F. C. Rushing, *chairman*	C. J. Koch
E. L. Bailey	T. C. Lloyd
E. C. Barnes	R. C. Moore
B. M. Cain	J. G. Noest
S. F. Henderson	C. P. Potter
Charles Kingsley, Jr.	P. H. Trickey

4. D-C Machinery Subcommittee

T. M. Linville, *chairman*	C. B. Hathaway
W. E. Clancy	V. P. Hessler
F. A. Compton	P. Lebenbaum
Lanier Greer	C. Lynn
L. N. Grier	D. Ramadanoff
J. L. Hamilton	J. F. Sellers

5. Single-Phase and Fractional-Horsepower Subcommittee

M. L. Schmidt, *chairman*	R. F. Munier
W. R. Appleman	P. H. Trickey
B. M. Cain	C. G. Veinott
I. M. Levy	N. S. Yost

6. Test Code Subcommittee

J. L. Fuller, *chairman* T. E. M. Carville T. C. Lloyd

7. Insulation Resistance Subcommittee

R. W. Wieseman, *chairman*	D. D. Higgins
H. R. Stewart, *secretary*	J. W. Jones
J. E. Allen	F. M. Porter
L. J. Berberich	V. E. Schlossler
E. B. Curdts	J. B. Swering
E. F. Dissmeyer	A. L. Van Emden
Orville E. Fawcett	C. O. Weilbaecher

Substations

G. S. Lunge, *chairman*, General Electric Company, central station engineering divisions, 1 River Road, Schenectady 5, N. Y.

H. Bany	W. L. Hiscox
H. Barber	K. B. Hoffman

(*Continued in next column*)

R. O. Bell	E. M. Hunter
F. J. Berger	S. C. Killian
M. K. Brown	I. F. Krughoff
M. V. Eardley	W. J. Lank
R. C. Ericson	N. G. Larson
G. P. Fallon	J. T. Lienert
J. M. Flanigen	W. M. McCauley
M. Fraresso	M. E. Reagan
S. F. French	S. L. Smith
H. F. Gidlund	K. L. Wheeler
C. D. Highleyman	G. S. Whitlow

SUBSTATIONS SUBCOMMITTEES

1. Executive Subcommittee

Scope: To plan and co-ordinate the activities of the main committee and its subcommittees including consideration of their scopes, program planning and assistance in selection of papers.

Main Committee Officers:

G. S. Lunge, *chairman*
R. C. Ericson, *vice-chairman*
M. Fraresso, *secretary*

(*Subcommittee chairmen and personnel to be selected.*)

2. Transmission Substation Subcommittee

Scope: Responsible for treatment of all problems of structural and electrical design, construction and arrangement of these substations known as transmission substations.

(*Subcommittee chairmen and personnel to be selected.*)

3. Distribution and Conversion Substation Subcommittee

Scope: Responsible for treatment of all problems of structural and electrical design, construction and arrangement of those substations known as distribution substations.

(*Subcommittee chairmen and personnel to be selected.*)

4. Automatic and Supervisory Control Subcommittee

Scope: Responsible for treatment of all problems relating to the development of automatic, remote, and manual control, and also fundamental electrical diagrams pertaining to substations.

(*Subcommittee chairmen and personnel to be selected.*)

Switchgear

F. A. Lane, *chairman*, American Gas and Electric Service Corporation, 30 Church Street, New York 8, N. Y.

C. K. Beyette	W. J. McLachlan
Harry Brown	R. G. Meyerand
J. S. Brown	E. F. Miller
E. A. Childerhose	V. G. Muzzey
H. W. Codding	Otto Naef
V. L. Cox	J. R. North
G. H. Doan	H. V. Nye
W. E. Enns	M. W. Rothpletz
K. J. C. Falck	H. H. Rudd
R. M. Ferrill	O. L. Sidenfaden
J. M. Geiger	F. V. Smith
W. J. Gilson	G. Stamper
W. D. Hardaway	A. Van Ryan
V. J. Hayes	J. H. Vivian
M. H. Hobbs	R. L. Webb
L. M. Hovey	C. E. Winegartner
C. L. Killgore	J. D. Wood
H. A. P. Langstaff	J. C. Woods
H. J. Lingal	S. W. Zimmerman

SWITCHGEAR SUBCOMMITTEES

1. Circuit Breaker Subcommittee

R. L. Webb, *chairman*	H. V. Nye
F. W. Cramer	F. V. Smith
R. M. Ferrill	J. H. Vivian
W. D. Hardaway	K. L. Wheeler
M. H. Hobbs	J. D. Wood
W. J. McLachlan	J. C. Woods
J. R. North	B. W. Wyman

The following working groups have been set up within this subcommittee:

A—Power circuit breakers.
B—Low-voltage air circuit breakers.
C—Automatic reclosers.
D—Calculations of short-circuit currents in low-voltage systems (A. E. Anderson, *chairman*).

2. Switchgear Assemblies Subcommittee

H. V. Nye, *chairman*	G. M. Reed
F. W. Cramer	H. H. Rudd
J. M. Geiger	B. K. Sturgis
C. H. Kreger	O. B. Vikorem
E. F. Miller	C. P. West
W. F. Wetmore	

3. Switches, Fuses, and Insulators Subcommittee

H. H. Rudd, *chairman* — H. L. Rawlins
K. J. C. Falck — R. L. Webb
A. H. Powell — J. C. Woods

The following working groups have been set up within this subcommittee:

A—Air switches and insulators (H. L. Rawlins, *chairman*).

B—Interrupter switches (H. H. Powell, *chairman*).

C—Fuses (R. L. Webb, *chairman*).

4. Subcommittee on High Voltage Switching (Where Out of Phase Voltages Exist at Time of Arc Interruption)

K. J. Falck, *chairman* — I. W. Gross
W. H. Black — E. L. Harder
W. E. Enns — M. H. Hobbs
R. M. Ferrill — C. B. Kelley
G. D. Floyd — H. V. Nye

5. Incompleted Projects

The incompleted projects carried over from the protective devices committee of 1947–8 are:

(*a*). Completion of Standards for automatic reclosers for a-c distribution circuits.

(*b*). Revision of Switchgear Assembly Standard 27.

(*c*). Review Standards for low-voltage air circuit breakers, which were issued for a one year trial period in December 1946.

(*d*). Complete work on calculations of short-circuit currents for low voltage.

(*e*). Complete work on revisions of short-circuit calculation and application factors for power circuit breakers

(*f*). Complete test code for power circuit breakers.

(*g*). Revise AIEE Standard 19 (ASA *C-37*) to include temperature limits for oilless circuit breakers.

(*h*). Study rating factors for oil and oilless circuit breakers.

(*i*). Complete revisions of AIEE Standard 22 for air switches and bus supports.

6. New Projects

(*a*). Study of H. H. Rudd's proposed supplement to AIEE Standard 2, Guiding Principles for Impulse Insulation Co-ordination.

(*b*). Prepare a test code for low-voltage circuit breakers.

(*c*). Prepare Standards for automatic short-circuiting devices.

(*d*). Co-operate with ASA *C-42* Committee on revision of "Definitions of Electrical Terms."

System Engineering

E. Wild, *chairman*, Commonwealth Edison Company, 72 West Adams Street, Chicago 90, Ill.

C. G. Adams — A. P. Hayward
C. P. Almon, Jr. — J. B. Hodtum
John Bankus — R. G. Hooke
G. Bissett — L. F. Hunt
M. L. Blair — L. R. Janes
R. Brandt — Alva A. Johnson
O. A. Demuth — C. B. Kelley
A. G. Dewars — M. H. Lovelady
G. D. Floyd — O. W. Manz, Jr.
A. P. Fugill — V. M. Marquis
E. E. George — C. W. Mayott
A. C. Gohlke — S. B. Morehouse
G. H. Groh — C. B. Signor
E. T. B. Gross — W. O. Smith
W. D. Hardaway — M. L. Waring
H. L. Harrington — G. S. Whitlow

SYSTEM ENGINEERING SUBCOMMITTEES

1. Administrative Subcommittee

Scope: To serve as an executive committee in the assignment of work to subcommittees, to expedite work and to arrange for preparation and presentation of papers at meetings.

E. Wild, *chairman* — L. F. Hunt
R. Brandt — B. M. Jones
H. L. Harrington — C. W. Mayott
A. P. Hayward — O. W. Manz, Jr.
R. G. Hooke — C. N. Metcalf

2. System Planning Subcommittee

Scope: Investigation and study of load growth and generation requirements, interconnection of systems methods of transmission and interconnection, location and optimum sizes of units, and general system planning studies.

H. L. Harrington, *chairman* — L. R. Janes
C. G. Adams — A. A. Johnson

(*Continued in next column*)

R. Brandt — B. M. Jones
A. G. Dewars — A. A. Kroneberg
A. P. Fugill — H. P. St. Clair
E. T. B. Gross — C. B. Signor
W. D. Hardaway — N. N. Smeloff
J. B. Hodtum — M. Ward
R. G. Hooke — M. L. Waring

3. System Operations Subcommittee

Scope: Investigation and study of load and kilovar dispatching, spinning reserve, emergency procedures, resynchronizing procedures, requirements and usage of communication equipment, safety "hold-off procedures," functions of intersystem operating committees, and other general studies for improvement of system operation.

O. W. Manz, Jr., *chairman* — G. H. Groh
J. Bankus — L. F. Hunt
G. Bissett — C. B. Kelley
M. L. Blair — F. Oppenheimer
O. A. Demuth — H. W. Phillips
G. D. Floyd — W. O. Smith

4. System Economics Subcommittee

Scope: Investigation and study of interconnection operation, economics of long high-voltage power transmission, co-ordination of operation of units in a plant, between plants in a system, and between systems and other economic studies for improved system operation.

A. P. Hayward, *chairman* — R. T. Purdy
E. C. Brown — J. A. Rose
E. E. George — C. W. Watchorn
V. M. Marquis — A. L. Williams

5. System Controls Subcommittee

Scope: Investigation and study of load-frequency control equipment and operation, voltage control, phase angle control, and other general studies of control methods to improve system operations.

R. Brandt, *chairman* — A. C. Gohlke
C. G. Adams — A. A. Johnson
C. P. Almon, Jr. — C. N. Metcalf
D. H. Cameron — S. B. Morehouse
T. E. Curtis — R. E. Pierce
G. S. Whitlow

6. Interconnection Contracts Subcommittee

Scope: Investigation and study as to important features of interconnection contracts, economic interchange, emergency requirements and metering requirements, and other matters of interest to improve interconnection relations.

C. W. Mayott, *chairman* — N. B. Hinson
E. D. Early — C. B. Kelley
E. E. George — M. H. Lovelady
G. A. Grimm — V. M. Marquis
R. Martindale

Transformers

H. B. Keath, *chairman*, Wagner Electric Corporation, 6400 Plymouth Avenue, St. Louis 14, Mo.

J. A. Adams — A. A. Johnson
F. S. Brown — D. L. Levine
M. K. Brown — H. C. Louis
R. J. Brown — C. M. Lovell
J. L. Cantwell — V. M. Montsinger
J. H. Chiles — M. H. Pratt
J. E. Clem — T. D. Reimers
G. W. Clothier — W. C. Sealey
Merrill DeMerit — F. L. Snyder
J. A. Elzi — Paul A. Vance
M. M. Ewell — F. J. Vogel
I. W. Gross — C. V. Waddington
J. B. Hodtum — H. H. Wagner
W. G. James — C. E. Winegartner

TRANSFORMERS SUBCOMMITTEES

1. Working Group on Co-ordinated Study of Life of Transformer Insulation

V. M. Montsinger, *chairman*

2. Working Group on Routine Measurement of Hot Spot Temperature Rise

W. C. Sealey, *chairman*

3. Instrument Transformer Subcommittee

Transformer Committee Representatives:

J. E. Clem, *chairman* — D. R. Lalb
W. K. Dickenson — E. C. Wentz

Relay Committee Representatives:

R. E. Cordray — W. A. Lewis
T. R. Halman — W. E. Marter
W. K. Sonneman

Switchgear Committee Representative:

H. Bany — J. M. Geiger
K. J. C. Falck — C. A. Woods

Instruments and Measurements Committee Representatives:

J. H. Chiles — J. P. Scott
A. B. Craig — F. B. Silsbee

Transmission and Distribution Committee Representatives:

J. B. Hodtum — L. M. Moore

Carrier-Current Committee Representative:

L. F. Kennedy

Working Group Chairmen:

W. E. Marter, relaying performance of current transformers
E. C. Wentz, test code
L. F. Kennedy, rating factors

4. Working Group on Accuracy of Voltage Regulator Control Devices

A. A. Johnson, *chairman*

5. Working Group on Operating Guides for Regulators

A. A. Johnson, *chairman*

6. Working Group on Short-Circuit Thermal Ratings of Induction and Step-Type Regulators

A. A. Johnson, *chairman*

7. Working Group on Magnetization Characteristics of Transformers

J. E. Clem, *chairman*

8. Working Group on Revision of Dielectric Tests

F. J. Vogel, *chairman*

9. Working Group on Temperature Limits of Silicon Insulation Used in Transformers

V. M. Montsinger, *chairman*

10. Working Group on Proposed Revision of A.S.A. Rules in Connection with Short-Circuit Requirements of Transformers

V. M. Montsinger, *chairman*

11. Working Group on Care and Operation of Dry Type Transformers

J. A. Adams, *chairman*

12. Working Group on Co-ordination of Insulation

J. E. Clem, *chairman*

Transmission and Distribution

C. F. Wagner, *chairman*, Westinghouse Electric Corporation, central station engineering department, East Pittsburgh, Pa.

C. E. Baugh — E. K. Huntington
P. L. Bellasch — Arthur A. Jones
E. D. Bent — C. H. Kraft
D. K. Blake — A. A. Kroneberg
B. Brady — J. T. Lusignan
T. J. Brosnan — D. W. Nethercut
H. E. Carson — J. E. O'Brien
Harold Cole — E. W. Oesterreich
E. R. Coulbourn — J. S. Parsons
S. B. Crary — C. K. Poarch
P. J. Croft — L. M. Robertson
A. E. Curtis — F. E. Sanford
H. A. Dambly — E. V. Sayles
A. E. Davison — A. N. Shealy
E. W. Dillard — A. E. Silver
W. B. Fisk — F. V. Smith
I. W. Gross — K. M. Smith
J. H. Hagenguth — E. C. Starr
K. E. Hapgood — H. M. Trueblood
E. R. Hendrickson — E. R. Whitehead
J. B. Hodtum — R. L. Witzke

TRANSMISSION AND DISTRIBUTION SUBCOMMITTEES

1. Capacitor Subcommittee

F. V. Smith, *chairman* — E. R. Hendrickson
M. I. Altmansky — R. E. Marbury
G. Appleman — N. A. Miller
C. E. Baugh — R. B. Miller
E. W. Dillard — C. E. Parks
R. H. Earle — W. L. Steinbarge
K. E. Hapgood — L. T. Williams

Projects:

(*a*). Revision of Standard *C55* (1934) of capacitors.

(*b*). Report on operating practice—fusing practice, circuit characteristics, grounding of neutral, telephone switching, and so forth, in an operating guide.

E. R. Hendrickson, *chairman*

(*c*). Study of troubles with capacitors.

C. E. Parks, *chairman*

2. Distribution Subcommittee

Harold Cole, *chairman* — D. W. Nethercut
D. K. Blake — E. W. Oesterreich

(*Continued on page 1790*)

T. J. Brosnan — J. S. Parsons
E. R. Hendrickson — R. R. Robinson
J. B. Hodtum — F. E. Sanford

Projects:

(a). Joint working group with transmission systems.
T. J. Brosnan — E. R. Hendrickson — J. S. Parsons

(b). Working group on primary systems.
D. K. Blake — L. M. Robertson — F. E. Sanford

(c). Distribution transformers to the customer.

3. General Systems Subcommittee

S. B. Crary, *chairman* — A. A. Kronebery
O. A. Demuth — E. L. McClure
L. B. LeVesconte — L. M. Robertson
R. G. Hooke — H. M. Trueblood
E. K. Huntington — R. L. Witzke

Projects:

(a). Subject committee on line outages (joint with EEI).
R. W. Caswell — M. H. Pratt (*for EEI*)
G. D. Floyd — H. M. Trueblood
K. W. Hapgood — R. L. Witzke

(b). Report on power system overvoltages.

(c). Frequency changeover.

(d). Contamination and life of insulators.

4. Lightning and Insulator Subcommittee

J. T. Lusignan, *chairman* — E. L. Harder
H. N. Ekvall — W. W. Lewis
H. A. Frey — G. D. McMann
I. W. Gross — S. K. Waldorf
E. R. Whitehead

Projects:

(a). Recommendations for lightningproof lines.
E. R. Whitehead, *chairman*

(b). Impulse characteristics of insulators, wood, and air in series.

(c). Insulator contamination and corrective measures.

(d). Insulator flashover characteristics.

5. Towers, Poles, and Conductors Subcommittee

A. E. Davison, *chairman* — E. L. Kanouse
N. K. Barr — W. I. Middleton
C. A. Booker — A. A. Osipovich
P. J. Croft — J. A. Rawls
A. L. Duna — A. S. Runciman
E. Hansson — E. J. Staubitz
G. W. Stickley

Industry Group

Industry Co-ordinating Committee

J. J. Orr, *chairman*, United States Rubber Company, 1230 Sixth Avenue, New York 20, N. Y.

T. R. Rhea
Victor Siegfried
Ex-officio
Chairmen of the seven following technical committees in the industry group

Chemical, Electrochemical, and Electrothermal Applications

F. R. Benedict, *chairman*, 930 Milton Avenue, Pittsburgh, Pa.
F. V. Andreae — R. J. Kuhn
F. T. Bowditch — E. H. Lamberger
J. D. Brance — D. H. Levy
W. H. Dickinson — J. A. McLellan
W. C. Dreyer — G. H. Orcutt
M. E. Gamble — Waldo Porter
Felix Glaza — R. L. Rayner
L. M. Goldsmith — T. R. Rhea
L. O. Grondahl — H. C. Riggs
W. E. Gutzwiller — L. W. Roush
E. A. Hanff — G. B. Scheer
C. W. Hansell — E. H. Scheick
J. D. Harper — E. O. Scott
T. G. Hieronymus — H. P. Sherer
J. E. Hobson — I. R. Smith
H. E. Houck — Joel Tompkins
J. D. Huntzberger — J. J. Unger
M. A. Hyde, Jr. — G. W. Vinal
Rollin Kennard — H. W. Wahlquist
E. L. Kirk — H. H. Zielinski

CHEMICAL, ELECTROCHEMICAL, AND ELECTROTHERMAL SUBCOMMITTEES

1. Arc Furnaces and Electrothermal Processes Subcommittee

E. H. Browning, Jr., *chairman* — E. A. Hanff
F. V. Andreae — A. R. Olirogge

(*Continued in next column*)

F. R. Benedict — E. Scheick
W. L. Bundy — H. H. Zielinski

2. Cathodic Protection Subcommittee

Scope: To develop the electrical engineering aspects of the application of cathodic protection. To promote a general understanding of those factors, under the control of designing and operating engineers, that contribute to corrosion and to its mitigation. To prepare a technical paper on the subject of electrical design from the standpoint of reduction of corrosion.

E. L. Kirk, *chairman* — I. A. Dennison
A. E. Archambault — L. J. Gorman
J. D. Brance — T. G. Hieronymus
A. B. Brooks — R. J. Kuhn
Guy Corfield — D. H. Levy
C. G. Cox — R. L. Rayner
H. W. Wahlquist

3. Electrolytic Processes Subcommittee

Scope: Treatment of all matters relative to electrolytic processes such as electrodeposition, electrolytic refining, electrolytic reduction, alkali chloride electrolysis, aqueous electrolytic processes. Such subjects as theory, technique, efficiency, plant, electrolytic cells, application of power conversion equipment, specialized equipment, and operating hazards are within the scope of this subcommittee.

W. E. Gutzwiller, *chairman* — Rollin Kennard
Felix Glaza — F. L. Lawton
J. D. Harper — G. H. Orcutt
H. E. Houck — Waldo Porter
F. L. Kaestle — G. B. Scheer
J. Tompkins

4. Petroleum Refining and Production Subcommittee

Lester Goldsmith, *chairman* — E. L. Hoyle
H. J. Appel — D. H. Levy
W. H. Dickinson — E. L. Nopper
J. B. Glasby — L. E. Priester

5. Storage Batteries Subcommittee

Scope: This subcommittee has as its function the fostering of technical papers and the establishment of AIEE Standards, where needed, on all phases of storage battery design and engineering.

H. C. Riggs, *chairman* — E. T. Rummel
J. D. Huntzberger — J. J. Unger
L. A. Murray — K. A. Vaughn
H. H. Zielinski

6. Chemical Industries Subcommittee

L. W. Roush, *chairman* — Felix Glaza — H. E. Houck

Electric Heating

G. W. Scott, Jr., *chairman*, Armstrong Cork Company, Lancaster, Pa.
E. L. Bailey — F. H. Mason
R. M. Baker — W. H. Meyer
E. H. Browning — L. R. Milburn
Harold Bunte — R. Neighbours
F. T. Chesnut — A. E. Opdenweyer
L. M. Duryee — C. E. Peck
R. H. Ellis — K. Pinder
P. H. Goodell — J. B. Rice
J. Grotsinger — W. C. Rudd
J. C. Handy — E. H. Scheick
E. A. Hanff — W. R. Schofield
J. B. Hodtum — G. S. Smith
L. P. Hynes — T. H. Story
T. P. Kinn — J. T. Thwaites
G. F. Leland — G. E. Walters
H. R. Winemiller

ELECTRIC HEATING SUBCOMMITTEES

1. Electronic Heating Subcommittee

Scope: Study of the problem of interference from electronic heating equipment (with the advance of the Electronic Heating Subcommittee, the Federal Communications Commission has formulated regulations regarding the allowable limit of radiation from electronic heating equipment). Formulation of the principles of good engineering practice to deal with intolerable interference. Development of an AIEE Standard for electronic heating equipment including definitions of electronic heating terms.

W. C. Rudd, *chairman* — T. R. Kennedy
W. R. G. Baker — T. P. Kinn
G. P. Bosomworth — W. H. Meyer
L. W. Chapin — Loyal R. Milburn
F. Chesnut — Eugene Mittelman
Harold E. Dinger — G. W. Scott, Jr.
L. M. Duryee — J. T. Thwaites
J. E. Eiselein — G. E. Walters
C. W. Frick — D. E. Watts
H. C. Gillespie — Otto Weitmann

(*Continued in next column*)

W. H. Hickok — H. R. Winemiller
R. J. Hunn — R. L. Uphoff — A. C. Wooldridge

2. Radiant Heating Subcommittee

Scope: Standardization of lamp-type heating in all its phases. The advantages and limitations of infrared heating will be emphasized for the benefit of the engineering profession. It will cover the construction, optics, thermodynamics, and safety considerations associated with all high temperature sources, correlation with other forms of electric heating, but not to include space heating.

Paul H. Goodell, *chairman* — S. G. Hibben
C. E. Russell, *secretary* — J. E. Johanson
L. J. Barber — E. A. Linaday
E. J. Bates — A. D. Moore
Earl Benson — C. T. Prendergast
P. O. Blackmore — G. W. Scott, Jr.
A. H. Canada — Lawrence Stout
Charles A. Casey — J. E. Sump
H. J. Garber — Ernest Upton
E. D. Haigler — W. H. Wagner

3. Subcommittee on Radiation Measurements Above 200 Megacycles

Scope: All methods of measuring radiation up to and above 200 megacycles are being studied. Actual experimental work in various laboratories is being undertaken to develop methods of measurement in the frequency ranges where a satisfactory method does not now exist and to improve methods in those ranges where some work has been done to date.

R. M. Baker, *chairman* — H. E. Dinger
H. H. Beitzer — J. E. Eiselein
Marvin Bock — C. W. Frick
R. E. Burgess — G. W. Scott, Jr.
E. W. Chapin — Ralph M. Showers
Lucien Clarke — A. J. Vadasz — H. E. Sorrows

4. Resistance Heating and Electric Furnaces Subcommittee

Scope: To study and promulgate information on the use of resistance heating and electric furnaces in industry including such standardization as may be necessary.

L. P. Hynes, *chairman* — A. G. Hotchkiss
F. E. Bash — C. E. Peck
Mark M. Greer — K. Pinder
J. C. Handy — David Y. Robinson
E. H. Scheick

Electric Welding

E. H. Vedder, *chairman*, Westinghouse Electric Corporation, P. O. Box 2025, Buffalo 5, N. Y.
E. M. Callender — J. R. Sellenberg
G. M. Chute — Sam Shiozawa
C. N. Clark — C. E. Smith
W. E. Crawford — H. W. Snyder
J. F. Deffenbaugh — H. I. Stanback
R. C. Freeman — E. F. Steinert
G. W. Garman — G. I. F. Theriault
J. C. Learman — H. W. Tietze
W. M. McKie — F. J. Wells
R. C. McMaster — B. L. Wise
C. M. Rhoades, Jr. — R. E. Young
F. Rothganger — Myron Zucker

ELECTRIC WELDING SUBCOMMITTEES

1. Power Supply for Resistance Welding Machines Subcommittee

Scope: Provision of basic information relating to power requirements and the effect of resistance welding load from the standpoint of both users and utilities. Outline economic considerations in the purchase and utilization, as well as provision of power, for welding including power factor correction, combined power and welding facilities, and so forth. Set up desirable practices and methods of procedure to be used in the selection of adequate power facilities for resistance welding.

C. M. Rhoades, Jr., *chairman* — R. S. Phair
W. H. Allen — C. E. Smith
W. G. Bostwick — J. L. Solomon
W. W. Brumby — C. B. Stadum
C. N. Clark — H. W. Tietze
E. F. Dissmeyer — Myron Zucker

2. Resistance Welding Subcommittee

C. E. Smith, *chairman* — C. N. Clark
E. M. Callender — Myron Zucker — G. W. Garman

3. Arc Welding Subcommittee

E. F. Steinert, *chairman* — R. R. LoBosco
C. N. Clark — G. I. MacGuffie
E. L. Hansen — H. W. Snyder

General Industry Applications

L. A. Umansky, *chairman*, General Electric Company, industrial engineering divisions, 1 River Road, Schenectady 5, N. Y.
B. T. Anderson — A. F. Lukens

(*Continued on page 1791*)

A. T. Bacheler — Joseph Mannele
S. A. Bobe — E. F. Mekelburg
D. C. Christison — J. F. Moore
J. M. Delfs — E. K. Murphy
J. C. Fink — D. R. Percival
A. W. Frankenfield — Kennard Pinder
J. A. Gienger — H. A. Rose
F. B. Haeussler — H. L. Smith
E. M. Hays — R. H. Smith
L. W. Herchenroeder — F. D. Snyder
K. W. John — R. F. Snyder
V. O. Johnson — Ray Stroppel
G. W. Knapp — W. B. Wigton

GENERAL INDUSTRY APPLICATIONS SUBCOMMITTEES

1. Machine Tools Subcommittee

W. B. Wigton, *chairman* — J. M. Dickenson
B. T. Anderson — L. W. Herchenroeder
E. L. Bailey — E. F. Mekelburg
J. M. Delfs — R. E. Stroppel — D. R. Percival

2. Materials Handling Subcommittee

E. M. Hays, *chairman* — D. C. Gray
E. L. Blankenbeker, *secretary* — R. W. Mallick
Fred W. Atz — A. H. Myles
O. M. Bundy — E. J. Posselt
M. A. de Ferranti — E. C. Rice
E. O. Dunham — C. B. Rissler
T. O. English — G. W. Yanney

3. Pulp and Paper Industry Subcommittee

G. W. Knapp, *chairman* — Floyd L. Davis
V. B. Baker — Oscar O. Fisk
H. B. Barrow — E. K. Murphy
A. C. Bird — H. Ostertag
D. C. Christison — Ray Smith — H. A. Rose

4. Rubber and Plastics Industries Subcommittee

K. W. John, *chairman* — V. O. Johnson
A. T. Bacheler — G. V. Kullgren
P. S. Bechtol — B. D. Morgan
B. J. Dalton — W. J. Secrest
J. A. Gienger — R. F. Snyder — H. L. Smith

5. Textile Industry Subcommittee

F. D. Snyder, *chairman* — L. T. Jester
S. A. Bobe — A. P. Lewis
R. J. Derviartini — D. McConnell
A. W. Frankenfield — Victor Sepavich
H. Haley — R. S. Stribling
F. B. Haeussler — H. C. Uhl

Industrial Control

J. D. Leitch, *chairman*, Electric Controller and Manufacturing Company, 2700 East 79th Street, Cleveland 4, Ohio

E. H. Alexander — E. F. Mekelburg
H. H. Angel — M. Michel
F. J. Bartholomew — T. B. Montgomery
L. J. Conover — E. E. Moyer
J. A. Cortelli — L. B. Murray
R. H. Ellis — H. L. Palmer
C. T. Evans — J. W. Picking
L. E. Fisher — L. T. Rader
D. K. Frost — G. H. Rendel
J. E. Gahagan — E. J. Rivoira
J. A. Gienger — J. B. Russell
G. W. Heumann — W. Schaichlin
K. W. John — R. E. Schuette
R. W. Jones — A. G. Turnbull
E. U. Lassen — E. H. Vedder
L. H. Mathias — H. R. Walker

INDUSTRIAL CONTROL SUBCOMMITTEES

1. Bibliography Subcommittee

R. W. Jones, *chairman*

2. Electronic Control Subcommittee

Scope: The treatment of all matters in which the dominant factors are the design, construction, and functioning of electronic industrial controls exclusive of those controls and functions that specifically are assigned to other technical committees.

H. L. Palmer, *chairman* — F. G. Logan
F. T. Bailey — E. B. McDowell
H. B. Black — J. W. Picking
S. L. Burgwin — V. J. Porter
C. J. Collom — K. P. Puchlowski
Ben Cooper — W. G. Roman
E. T. Davis — C. A. Schurr
W. H. Elliot — W. W. Snyder
William Few — H. I. Stanback
E. W. Hutton — B. B. Stuart
L. U. C. Kelling — C. M. Summers
O. W. Livingston — B. F. Tellkamp

Working Groups:

(2-1). Electronic Control of D-C Motors

J. W. Picking, *chairman* — William Few
H. B. Black — F. G. Logan
C. J. Collom — W. G. Roman
Ben Cooper — H. I. Stanback
W. H. Elliot — B. B. Stuart
B. F. Tellkamp

(2-2). Photoelectric Pickup Systems

L. U. C. Kelling, *chairman* — F. T. Bailey

(2-3). Electronic Relaying Devices

E. B. McDowell, *chairman* — C. A. Schurr
K. P. Puchlowski — B. F. Tellkamp

(2-4). Electronic Regulators and Regulating Systems

O. W. Livingston, *chairman* — W. H. Elliot
H. B. Black — William Few
S. L. Burgwin — F. G. Logan
E. T. Davis — J. W. Picking
W. W. Snyder

(2-5). Electronic Control of A-C Power

E. W. Hutton, *chairman* — F. G. Logan
H. B. Black — W. G. Roman
W. H. Elliot — B. F. Tellkamp

3. Standards Subcommittee

Scope: This subcommittee will prepare proposals for revised and new Standards pertaining to industrial control in which AIEE is interested, especially AIEE Standard 15 which is also ASA Standard C19.1. Such proposals are in preparation to action taken by official AIEE members on the respective ASA committees. The work of co-ordinating is carried on by the subcommittee chairman who assembles working groups from time to time as the need for action on existing or new Standards arises.

G. W. Heumann, *chairman*

4. Test Codes Subcommittee

Scope: The proposed test code should contain recommendations for test procedure and test methods, as applied to industrial control equipment. The test methods recommended should be such that the tests made at different times and by different laboratories will be comparable and significant. It is desirable that the test procedures be such that the results of the tests may be interpreted and expressed in some defined scale of comparison, but it is not the purpose of the test code to set standards of acceptability. Neither should the test code attempt to determine or specify what type of investigation need be made on any given type of apparatus. It is the consensus of opinion that the efforts of the subcommittee should be concentrated on the more fundamental tests relating to basic design rather than on routine production tests.

C. T. Evans, *chairman* — H. E. Nason
D. K. Frost — W. E. Pakala
B. W. Jones — H. E. Ryan
C. A. Schaefer

Industrial Power Systems

D. L. Beeman, *chairman*, General Electric Company, industrial engineering divisions, Schenectady 5, N. Y.

W. M. Ballenger — J. S. Morgan
H. G. Barnett — W. A. Mosteller
W. C. Bloomquist — J. S. Parsons
E. S. Dibble — R. C. Peters
Felix Glass — C. G. Pionnasen
J. S. Gault — Dick Ray
W. N. Goodridge — W. H. Rollman
W. S. Gordon, Jr. — F. Rothganger
D. C. Gray — R. C. Settersrom
L. N. Grier — R. R. Shollenberger
W. R. Harmer — J. F. Spease
C. F. Hedlund — H. C. Swannell
C. R. Johnson — T. O. Sweatt
R. E. Johnson — B. F. Thomas
G. M. Lathrop — S. A. Warner
M. C. Mapes — R. W. Watson
A. E. Marshall — William Zelley
J. L. McKeever — T. O. Zittel

INDUSTRIAL POWER SYSTEMS SUBCOMMITTEES

1. Subcommittee on Interior Wiring Design for Commercial Buildings

B. F. Thomas, Jr., *chairman* — Ralph C. Hodges
L. W. McCullough, *secretary* — R. H. Kaufmann
F. R. Benedict — George K. Perley
C. D. Bratiotis — L. C. Peterman
Leo H. Cleary — H. F. Richardson
Allan Coggeshall — C. W. Schemm
W. T. Crosman — C. F. Scott
R. F. Davis — B. Z. Segall
V. E. Dodson — Herbert Speight
C. F. Hedlund — Howard R. Stevenson
James A. Heffernan — T. O. Sweatt
W. Weinerth

2. Subcommittee on Revision of Electric Power Distribution for Industrial Plants

John Grotzinger, *chairman* — L. E. Fisher

(Continued in next column)

J. A. Arberry — C. R. Johnson
G. E. Baker — N. B. Lainge
H. G. Barnett — S. W. Luther
W. C. Bloomquist — R. B. McKinley
E. T. Carlson — J. S. Parsons
R. F. Davis — R. C. R. Schulze
Wm. Deans — E. E. Turkington
D. D. Douglass — R. J. Wiseman

3. Transformer Voltage Ratios Subcommittee

H. G. Barnett, *chairman* — J. Grotzinger
D. L. Beeman — K. Pinder
S. F. French — T. O. Sweatt
C. C. Whipple

Mining and Metal Industry

F. W. Cramer, *chairman*, Carnegie-Illinois Steel Corporation, Carnegie Building, Fifth Avenue, Pittsburgh 19, Pa.

G. Bright — R. C. McMaster
M. K. Clay — W. E. Miller
R. J. Corfield — T. B. Montgomery
J. A. Cortelli — A. C. Muir
E. W. Davis — H. P. Musser
J. M. Downie — Bailey E. Price
J. H. Edwards — D. E. Renshaw
R. H. Ellis — E. G. Schlup
J. R. Erbe — F. O. Schnure
Cecil Farrow — Victor Siegfried
James J. Fitzgibbon — O. J. Swanson
Lanier Greer — C. L. Tyler
L. N. Grier — T. R. Weichel
W. R. Harris — A. J. Whitcomb
L. H. James — C. O. Wood
C. F. King, Jr. — I. O. Zittel

MINING AND METAL INDUSTRY SUBCOMMITTEES

1. Metal Industries Subcommittee

T. B. Montgomery, *chairman* — C. F. King
J. A. Cortelli — W. E. Miller
R. H. Ellis — Bailey Price
J. R. Erbe — E. G. Schlup
Cecil Farrow — F. O. Schnure
L. N. Grier — Victor Siegfried
W. R. Harris — A. J. Whitcomb

2. Mining Subcommittee

A. C. Muir, *chairman* — James J. Fitzgibbon
Graham Bright — R. C. McMaster
M. K. Clay — H. P. Musser
R. J. Corfield — D. E. Renshaw
E. W. Davis — O. J. Swanson
John M. Downie — C. L. Tyler
J. H. Edwards — T. R. Weichel
L. H. James — C. O. Wood

Communication and Science Group

Communication and Science Co-ordinating Committee

J. D. Tebo, *chairman*, Bell Telephone Laboratories, 463 West St., New York 14, N. Y.

J. L. Callahan — I. Melville Stein

Ex-officio

Chairmen of the eight following technical committees in the communication and science group

Basic Sciences

Walther Richter, *chairman*, Allis-Chalmers Manufacturing Company, West Allis, Wis.

J. A. Becker — W. A. Lewis
J. G. Brainerd — M. G. Malti
C. R. Burrows — W. H. MacWilliams, Jr.
F. M. Clark — G. D. McCann
C. Concordia — K. W. Miller
P. C. Cromwell — W. E. Phillips
A. V. Eastman — H. J. Plumley
E. A. Gaugler — J. B. Russell
W. C. Hall — W. J. Seeley
C. R. Hanna — J. J. Smith
C. W. Hansell — L. A. Smith
F. K. Harris — V. G. Smith
H. L. Hazen — F. G. Tappan
N. S. Hibshman — J. D. Tebo
T. J. Higgins — F. E. Terman
W. C. Johnson — G. S. Timoshenko
T. D. Yensen

BASIC SCIENCES SUBCOMMITTEES

1. Applied Mathematics Subcommittee

Scope: To furnish needed co-operation between mathematicians and engineers, preferably by bringing specific engineering problems to the attention of mathematicians for solution rather than to consider only general problems which might be discussed from an abstract viewpoint. Members of the American Mathematical Society

are invited to join with this subcommittee in mutually advantageous conferences and sessions.

M. G. Malti, *chairman* — Henry B. Hanateen
P. L. Alger — J. J. Smith
Harry Sohon

2. Electric Circuit Theory Subcommittee

Scope: Considerable work in circuit theory has been done, particularly as a result of the war effort. The function of this subcommittee is to make a thorough review of recent circuit theory developments in all fields directed toward the publication of this material and also to study circuit theory definitions which are needed urgently in view of the almost complete lack of standard circuit theory definitions existing at the present time.

T. J. Higgins, *chairman* — F. J. Maginniss
J. G. Brainerd — W. O. Osbon
R. L. Dietzold — E. B. Payne
E. A. Guillemin — W. E. Phillips
E. Weber

3. Energy Sources Subcommittee

Scope: The great impetus given to new methods of supplying electric power by developments in nuclear energy has suggested that all known methods of producing electric power should be reviewed in the light of present-day knowledge. This subcommittee is conducting conferences to review the various known means of electric energy generation, efforts being made to prepare for publication papers by outstanding experts in their respective fields.

W. A. Lewis, *chairman* — L. W. Matsch
W. C. Brown — Walther Richter
M. A. Gartens — J. J. Smith
C. R. Hanna — B. R. Teare
J. D. Tebo

4. Electrical Properties of Solids Subcommittee

Scope: Treatment of the theories explaining the electrical properties of various types of solid materials commonly used in electrical engineering, such as thermionic emission, semiconductors, dielectrics, and magnetism.

Joseph A. Becker, *chairman* — K. Lark-Horovitz
Stephan Angello — P. H. Miller, Jr.
J. P. Barton — Fred Seitz
Saul Dushman — Lloyd Smith
R. W. Engstrom — A. Von Hippel
F. K. Harris — Dean W. Wooldridge

5. Subcommittee on Magnetics

T. D. Yensen, *chairman* — E. A. Gaugler
J. P. Barton — S. L. Quimby
R. M. Bozorth — W. E. Ruder
G. H. Cole — Van Vleck
H. G. Zambell

6. Subcommittee on Electrical Properties of Liquids and Gases

(*Personnel to be selected*)

Communication

Rothwell E. Smith, *chairman*, International Telephone and Telegraph Corp., 67 Broad St., New York 4, N. Y.

L. G. Abraham — P. L. Johnson
H. A. Affel — E. W. Kenefake
A. L. Albert — R. H. Kline
W. M. Allen — H. P. Lawther
G. M. K. Baker — M. Levy
L. D. Becken — G. A. Locke
J. D. Booth — R. E. Mathes
F. B. Bramhall — G. R. Messmer
A. J. Busch — J. L. Middlebrooks
I. F. Byrnes — F. E. Norris
J. L. Callahan — R. R. O'Connor
J. B. Coleman — L. G. Pacent
L. G. Cumming — E. G. Ports
C. E. Dean — R. H. Ranger
M. Eastham — G. B. Ransom
H. E. Ellithorn — W. A. Ready
A. E. Frost — F. M. Rives
J. C. Gaudio — H. I. Romnes
D. G. Geiger — G. T. Royden
P. C. Goldmark — A. L. Rumsey
T. T. Goldsmith, Jr. — J. B. Russell
G. H. Gray — R. E. Shelby
L. B. Grew — A. B. Smith
H. H. Haglund — J. E. Smith
W. D. Hailes — W. T. Smith
L. C. Holmes — S. C. Spielman
E. M. Johnson — R. B. Vaile, Jr.
W. E. Vellines, Jr.

COMMUNICATION SUBCOMMITTEES

1. Co-ordinating Committee

Scope: To act as liaison between the technical program committee and the working units of the communication committee.

R. E. Smith, *chairman* — F. B. Bramhall, *secretary*
J. L. Callahan, *junior past chairman*
H. I. Romnes, *vice-chairman*

Subcommittee chairmen:

H. A. Affel — H. H. Haglund
J. D. Booth — F. G. Ports
A. J. Busch — F. M. Rives
G. H. Gray — R. E. Shelby
S. C. Spielman

2. Communications Standards Subcommittee

Scope: To co-ordinate with other working units on standards in so far as it may concern communications.

G. H. Gray, *chairman*

3. Communication Switching Systems Subcommittee

Scope: Embodies telephone switching systems such as crossbar, panel, rotary and step-by-step and includes all forms of telegraph switching systems such as employed in handling switched telegraph message traffic.

A. J. Busch, *chairman* — P. L. Johnson
A. E. Frost — H. P. Lawther
D. G. Geiger — F. E. Norris
G. H. Gray — Arthur Bessey Smith
L. C. Holmes — D. L. Solomon

4. Wire Communication Systems Subcommittee

Scope: Covers wire transmission systems and associated apparatus as applied to open wire lines, land and submarine cables for providing telephone, telegraph, broadcast, and television program services.

H. A. Affel, *chairman* — G. H. Gray
L. G. Abraham — H. H. Haglund
Arthur L. Albert — R. R. O'Connor
W. M. Allen — G. B. Ransom
H. E. Ellithorn — A. L. Rumsey
Arthur Bessey Smith

5. Home Radio Receivers Subcommittee

Scope: This subcommittee comprises activities related to amplitude modulation, frequency modulation, and television receivers used for the reception from radio-broadcasting stations.

S. C. Spielman, *chairman* — P. C. Goldmark
J. B. Coleman — T. T. Goldsmith, Jr.
L. G. Cumming — E. W. Kenefake
C. E. Dean — M. Levy
J. C. Gaudio — H. W. Schaefer

6. Power Line Carrier Systems Subcommittee

Scope: This subcommittee would join with the power group in handling all activities related to the use of carrier currents by power companies in their operations.

F. M. Rives, *chairman* — W. D. Hailes
J. D. Booth — G. R. Messmer
W. T. Smith

7. Radiobroadcasting Systems Subcommittee

Scope: This subcommittee would cover amplitude modulation, frequency modulation, and television broadcasting stations, studio equipment, television cameras, studio-transmitter links, and anything else related to the broadcasting of programs for entertainment or instruction.

R. E. Shelby, *chairman* — T. T. Goldsmith, Jr.
G. M. K. Baker — E. M. Johnson
J. B. Coleman — E. W. Kenefake
P. C. Goldmark — J. L. Middlebrooks
J. Ernest Smith

8. Radio Communication Systems Subcommittee

Scope: This subcommittee would cover radio communication systems of all kinds such as radio relay for telephone, television or telegraph; mobile systems for automobiles, ships, or airplanes; and point-to-point systems for telephone or telegraph.

E. G. Ports, *chairman* — T. T. Goldsmith, Jr.
G. T. Royden, *vice-chairman* — E. W. Kenefake
E. D. Becken — G. R. Messmer
E. M. Boone — R. H. Ranger
I. F. Byrnes — John B. Russell
J. Ernest Smith

9. Record Communications Subcommittee

Scope: This subcommittee would handle facsimile telephoto, magnetic recording, teletypewriters, and other similar communications involving the making of a record.

H. H. Haglund, *chairman* — G. A. Locke
E. D. Becken — R. E. Mathes
J. O. Carr — R. H. Ranger
G. H. Gray — Arthur Bessey Smith
L. C. Holmes — R. B. Vaile, Jr.

10. Special Communication Applications Subcommittee

Scope: This subcommittee would handle miscellaneous activities which do not fall within the scope of the other committees such as hearing aids, radar, and sonar.

J. D. Booth, *chairman* — W. D. Hailes
R. H. Kline, *vice-chairman* — E. W. Kenefake
I. F. Byrnes — L. G. Pacent
J. B. Coleman — W. A. Ready
Melville Eastham — R. B. Vaile, Jr.

Computing Devices

Charles Concordia, *chairman*, central station engineering divisions, General Electric Company, 1 River Road, Schenectady 5, N. Y.

J. G. Brainerd — W. H. MacWilliams, Jr.
S. H. Caldwell — J. W. Mauchly
F. I. Harder — G. D. McCann
W. C. Johnson — J. C. McPherson

COMPUTING DEVICES SUBCOMMITTEES

1. Digital Computers Subcommittee

Doctor John W. Mauchly, *chairman*

2. Continuous-Variable Computers Subcommittee

Doctor E. L. Harder, *chairman*

Electronic Power Converters

H. Winograd, *chairman*, Allis-Chalmers Manufacturing Company, electrical department, Milwaukee 1, Wis.

H. R. Blomquist — D. E. Marshall
W. F. Bonner — A. J. Maslin
J. L. Boyer — L. W. Morton
J. H. Cox — R. A. Nelson
F. W. Cramer — M. E. Reagan
J. B. Donnelly — W. J. L. Rupprecht
Wm. Fraser — A. Schmidt, Jr.
W. E. Gutzwiller — W. C. Sealey
P. L. Hartsock — S. L. Smith
C. C. Herskind — H. C. Steiner
H. E. Houck — O. J. Swanson
G. N. Hughes — T. A. Taylor
Otto Jensen — J. T. Thwaites
C. R. Marcum — Joel Tompkins
C. H. Willis

ELECTRONIC POWER CONVERTERS SUBCOMMITTEES

1. Policy and Planning Subcommittee

Scope: The function of this subcommittee is to plan and co-ordinate the activities of the main committee and its subcommittees. It will consist of the officers and the preceding chairman of the main committee, the chairmen of the subcommittees, and any other committee members designated by the chairman.

Main Committee Officers:
H. Winograd, *chairman*
C. C. Herskind, *vice-chairman*
H. C. Steiner, *secretary*
C. H. Willis, *preceding chairman*

Subcommittee Chairmen:
C. R. Marcum — A. J. Maslin
D. E. Marshall — L. W. Morton
Joel Tompkins

2. Electronic Converter Application Subcommittee

Scope: This subcommittee will handle matters relating to the application and operation of electronic power converters, such as rating, installation, operation, maintenance, inductive co-ordination.

L. W. Morton, *chairman* — W. E. Gutzwiller
Joel Tompkins, *co-chairman* — H. E. Houck
F. W. Cramer — W. J. L. Rupprecht
J. B. Donnelly — S. L. Smith
Wm. Fraser — O. J. Swanson
N. W. Geist — T. A. Taylor
J. T. Thwaites

3. Electronic Converter Circuits Subcommittee

Scope: This subcommittee will handle matters relating to circuit theory, protection, and control of electronic power converters. It will co-operate with the other subcommittees and with other AIEE committees (such as electronics, switchgear, protective devices substations) on matters of mutual interest.

C. C. Herskind, *chairman* — G. F. Jones
W. F. Bonner — R. A. Nelson
J. L. Boyer — M. E. Reagan
E. V. De Blieux — A. Schmidt, Jr.
I. K. Dortort — T. A. Taylor
G. N. Hughes — C. H. Willis
H. Winograd

4. Metallic Rectifiers Subcommittee

Scope: This subcommittee so far has completed a set of standard definitions, a bibliography, and a patent list on metallic rectifiers. It is working now on a test code and also is collaborating with the United States Army and Navy in connection with the issuance of a Joint Army-Navy specification on metallic rectifiers. This subcommittee has future plans to issue standards for metallic rectifiers, as well as delve into the theoretical aspects of these rectifiers.

L. O. Grondahl, *chairman* — C. W. Hansell

(*Continued on page 1793*)

E. A. Harty, *secretary* — C. C. Herskind
W. F. Bonner — W. E. Phillips
L. W. Burton — N. Y. Priesman
P. G. Cobb — C. G. Ramsey
M. E. Gamble — I. R. Smith
K. S. Geiges — D. Trucksess
E. A. Groeteke — J. Yarmack
C. E. Hamann — S. Zwerling

5. Papers and Speakers Subcommittee

Scope: This subcommittee will complete the bibliography on electronic power converters and will keep it up to date with annual supplements. It will make recommendations on subjects for technical papers and promote the preparation of such papers. It will prepare information on the availability of speakers and educational material on electronic power converters, as an aid to schools, AIEE Sections, and discussion groups.

C. R. Marcum, *chairman* — J. T. Thwaites
J. B. Rice — H. E. Zuvers

6. Rectifier Transformers Subcommittee

Scope: This subcommittee will handle matters relating to transformer equipment used for electronic power converters. It will maintain liaison with the AIEE transformer committee, to keep the two committees informed on matters of mutual interest.

A. J. Maslin, *chairman* — E. V. DeBlieux
W. C. Sealey

7. Rectifying Devices Subcommittee

Scope: This subcommittee will handle matters relating to design and characteristics of rectifying devices used for electronic power converters. It will maintain liaison and co-operate with other technical committees of the AIEE and other organizations which carry on activities relating to such rectifying devices, and it will keep the electronic power converter committee informed on such activities.

D. E. Marshall, *chairman*

8. West-Coast Subcommittee

J. H. Cox, *chairman*

9. Other Projects from Last Year

(*a*). Preparation of report on protection of electronic power converters. By electronic converter circuits subcommittee; C. C. Herskind, chairman of working group.

(*b*). Bibliography on electronic power converters. By papers and speakers subcommittee; C. R. Marcum, chairman of working group.

(*c*). 1. Prepare forms for collecting application, operating, and maintenance data on mercury-arc power converters.

2. Collect data on a-c system characteristics and load characteristics in rectifier installations for various industries.

3. Power metering in rectifier installations. By electronic converter application subcommittee; L. W. Morton, chairman.

(*d*). Prepare report on inductive co-ordination relating to d-c side of rectifier installations. By electronic converter application subcommittee; T. A. Taylor, chairman of working group.

Electronics

C. H. Willis, *chairman*, Princeton University, Princeton, N. J.

G. M. K. Baker — O. W. Livingston
W. R. G. Baker — D. E. Marshall
R. Bennett — R. C. Mason
E. M. Boone — F. T. McNamara
C. J. Breitwieser — H. R. Meahl
C. B. Brown — G. A. Morton
G. H. Browning — B. K. Northrop
C. V. Bullen — J. K. Nunan
R. S. Burnap — D. Packard
W. R. Clark — H. L. Palmer
L. G. Cowles — G. W. Penney
G. J. Crowdes — W. H. Pickering
H. F. Dart — O. W. Pike
E. V. DeBlieux — A. J. Quigley
W. G. Dow — J. G. Reid, Jr.
A. V. Eastman — L. E. Reukema
G. V. Elizroth — J. D. Ryder
R. Feldt — E. T. Sherwood
D. G. Fink — H. B. Slade
K. S. Geiges — S. W. Smith
W. A. Geohegan — T. Spooner
E. W. Greenfield — H. C. Steiner
E. R. Haberland — C. M. Summers
L. P. Haner — A. A. Sylvane
J. D. Heibel — E. R. Thomas
J. E. Hobson — J. T. Thwaites
J. R. Hyneman — F. N. Tompkins
T. P. Kinn — D. E. Trucksess
W. H. Lee — D. C. Ulrey
W. A. Leidigh — W. C. White
J. D. Leitch — H. Winograd
A. M. Zarem

ELECTRONICS SUBCOMMITTEES

1. Electronic Aids to Navigation Subcommittee

Scope: The formulation of definitions of radio and electronic navigational terms. This work is being co-ordinated with the radio technical commission for aeronautics. In future months it is expected that the committee will undertake to formulate standards of testing various radio and electrical navigation systems.
(Personnel not yet selected)

2. Electronic Precipitation Subcommittee

Scope:

1. Electrical precipitation of dust, both in air conditioning and in the removal of high concentrations of dust fume and smoke which generally has been called Cottrell precipitation.
2. Electrostatic painting and "detearing."
3. Electrostatic separation of solids.
4. Electrostatic application of abrasives and other substances in manufacturing processes.
5. Static problems in industry.

(G. W. Penney, *chairman*)

3. Electronic Papers, Meetings and Section Contacts Subcommittee

Scope: Encourages and initiates the preparation of papers on any phase of electronics.
W. C. White, *chairman*

4. High-Frequency Conductors, Cables, and Connectors Subcommittee

Scope: The subcommittee has under consideration possible standardization, procurement of technical papers, and liaison work with other technical sections in connection with high-frequency cables, conductors, and connectors. The scope of this subcommittee also will include wave guides. The subcommittee has been actively considering coaxial cables, other high-frequency wires and connectors, and test methods.
G. J. Crowdes, *chairman*

5. Hot-Cathode Electronic Power Converters Subcommittee

Scope: Preparation of standards that apply to the following types of converters: rectifiers utilizing hot cathode gas or vacuum tubes and inverters utilizing hot cathode gas tubes. This scope excludes applications in oscillator circuits and radio receivers.
D. E. Trucksess, *chairman*

6. Subcommittee for Liaison with IRE

R. S. Burnap, *chairman*

7. Subcommittee for Liaison with JETEC (Joint Electron Tube Engineering Council)

O. W. Pike, *chairman*

8. West Coast Subcommittee

W. H. Pickering, *chairman*

9. Canadian Liaison Subcommittee

J. E. Thwaites, *chairman*

10. Electronic Education Subcommittee

J. D. Ryder, *chairman*

11. Electronic Aids to Medicine Subcommittee

Scope: This subcommittee will attempt to co-ordinate medical and engineering development, acquainting the engineering profession with medical problems requiring engineering development, and acquainting the medical profession with possibilities in solution of their problems.
W. A. Geohegan, *chairman*

12. X-Ray Tubes and Apparatus Subcommittee

Scope: Matters pertaining to X-ray tubes, rectifier tubes used in X-ray high-voltage generators, and other electron tubes used in X-ray apparatus and accessories. It contemplates work on such projects as standardizing the method of specifying the ratings and characteristics of X-ray and rectifier tubes; standardizing the symbols and form of presenting the wiring diagrams for X-ray generators; and standardizing the method of specifying the characteristics and ratings of X-ray transformers and generators.
Scott W. Smith, *chairman*

13. Electron Tubes Subcommittee

Scope: Treatment of all technical matters relating to the design, construction, test, and operation of electron tubes for industrial use. The committee is starting the preparation of standards. These standards will include sections on high vacuum tubes, cathode-ray tubes, gas-filled thermionic and cold cathode tubes, phototubes, and mercury-pool cathode tubes. All pertinent information such as definitions, standards, test codes, and application practice codes that is necessary to define electron tubes technically is to be included.
H. C. Steiner, *chairman*

Working Groups:

(*13-1*). High Vacuum Tubes
(*13-2*) Cathode-Ray Tubes
(*13-3*). Gas-Filled Thermionic and Cold Cathode Tubes—Phototubes
(*13-4*). Mercury-Pool Cathode Tubes

14. Electronic Standards and Definitions Subcommittee

Scope: It is the function of this subcommittee to assist the various electronic subcommittees in co-ordinating their standardizing efforts and to get them into the proper form and channels, if they are to become AIEE or American Standards. A part of this subcommittee's function is educational, in that it is attempting to show how standardization is accomplished, what national societies and associations are concerned, and how their activities are correlated.
T. Spooner, *chairman*

15. Electronic Aids to Geophysics

L. G. Cowles, *chairman*

16. Electronic Preparation and Preservation of Food
(Personnel not yet selected)

17. Infrared Applications

A. H. Canada, *chairman*

18. Liaison with Nucleonics

G. A. Morton, *chairman*

Instruments and Measurements

E. I. Green, *chairman*, Bell Telephone Laboratories, Inc., 463 West Street, New York 14, N. Y.

R. C. Bailey — H. C. Koenig
P. A. Borden — Everett S. Lee
H. H. Brauer — B. E. Lenehan

L. A. Burckmyer, Jr. — H. C. Martin
S. H. Caldwell — L. W. Matsch
J. H. Chiles — C. E. Melville
W. R. Clark — J. H. Miller
J. E. Clem — J. A. Morris
A. B. Craig — J. G. Reid, Jr.
C. L. Dawes — R. D. Richardson
F. C. Doble — J. B. Russell
E. D. Doyle — C. F. Savage
C. K. Duff — J. P. Scott
G. W. Dunlap — F. B. Silsbee
W. N. Eddy — D. B. Sinclair
F. J. Gaffney — M. B. Stout
T. S. Gray — E. L. Tornquist
C. M. Hathaway — W. R. Turner
G. B. Hoadley — J. M. Vanderleck
E. B. Kipp — L. K. Yerger
W. G. Knickerbocker — D. A. Young
A. E. Knowlton — C. J. Zeller

INSTRUMENTS AND MEASUREMENTS SUBCOMMITTEES

1. Subcommittee on Definitions

C. L. Dawes, *chairman* — W. N. Goodwin, Jr.
J. E. Clem — Everett S. Lee
Arthur B. Craig — B. E. Lenehan
H. C. Dickinson — P. MacGahan
F. B. Silsbee

2. Subcommittee on Electrical Tests on Dielectrics in the Field

F. C. Doble, *chairman* — E. D. Doyle
D. L. Brown — W. N. Eddy
A. L. Brownlee — I. W. Gross
C. T. Burke — Everett S. Lee
E. B. Curdu — D. B. Sinclair
Chester L. Dawes — G. M. L. Sommerman
L. Wetherill

3. Subcommittee on High-Frequency Measurements

F. J. Gaffney, *chairman* — G. B. Hoadley
I. G. Easton — H. Lyons
E. P. Felch, Jr. — H. R. Meahl
F. Hamberger, Jr. — H. E. Webber
H. A. Wheeler

4. Subcommittee on Marking of Varmeters and Related Instruments

Arthur B. Craig, *chairman* — Walter G. Knickerbocker
A. L. Brownlee — A. E. Knowlton
A. L. Carvill — F. B. Silsbee
E. B. Kipp — H. B. Smith

5. Subcommittee on Master Test Code for Resistance Measurements

F. B. Silsbee, *chairman* — Everett S. Lee
E. D. Doyle — L. W. Matsch
D. B. Sinclair

6. Subcommittee on Master Test Code for Temperature Measurements

L. A. Burckmyer, Jr., *chairman* — A. K. Jocks
F. A. Borden — R. D. Richardson
E. D. Doyle — M. D. Ross
W. R. Hough — S. S. Stack

7. Subcommittee on Revision of AIEE Standard 4 (Measurement of Test Voltage in Dielectric Tests)

J. T. Lusignan, *chairman* — J. H. Hagenguth
P. L. Bellaschi — W. B. Kouwenhoven

(*Continued on page 1794*)

A. L. Brownlee — R. S. Lapp
J. S. Carroll — W. W. Lewis
J. J. Clark — M. Newman
J. E. Clem — W. C. Sealey
E. W. Davis — F. B. Silsbee
C. M. Foust — W. T. Smith
H. A. Frey — R. W. Sorensen
I. W. Gross — W. L. Teague
S. W. Zimmerman

8. Subcommittee on Revision of C 39 (Electric Indicating Instruments)

H. C. Koenig, *chairman* — C. F. Savage
R. D. Hickok, Sr. — F. B. Silsbee
E. S. Lee — J. M. Vanderleck
P. MacGahan — D. A. Young
J. H. Miller — C. J. Zeller

9. Subcommittee on Watt-hour Meters

W. G. Knickerbocker, *chairman* — H. C. Koenig
A. L. Brownlee — B. E. Kenehan
D. T. Canfield — G. B. M. Robertson (AEIC) ex officio
A. B. Craig — C. F. Savage
F. C. Holtz — M. B. Stout
H. M. Johnson — E. L. Tornquist
L. K. Yerger

Nucleonics

J. J. Smith, *chairman*, General Electric Company, general engineering and consulting laboratory, Schenectady, N. Y.
W. E. Barbour, Jr. — M. M. Hubbard
R. C. Bergvall — Harvard Hull
H. W. Bibber — J. A. Hutcheson
H. W. Brackney — E. H. Krieg
L. J. Bulliet — H. B. Marvin
L. W. Chubb — B. R. Prentice
J. M. Cork — Walther Richter
W. F. Davidson — Frederick Seitz
G. W. Dunlap — Abe Tiles
J. R. Dunning — J. G. Trump
I. A. Getting — R. E. Watson
T. S. Gray — J. T. Wilson

NUCLEONICS SUBCOMMITTEE

1. Nucleonics Instrumentation and Control
G. W. Dunlap, *chairman*

2. Studies of Nuclear Theory
J. T. Wilson, Jr., *chairman*

3. Isotopic Tracers
W. E. Barbour, *chairman*

4. Health Safety and Protection Against Radiation

Therapeutics

E. E. Charlton, *chairman*, General Electric Company, research laboratory, Schenectady 5, N. Y.
F. B. Clausen — G. E. Maxim
H. J. Holmquest — H. D. Moreland
Roy Kegerreis — C. M. Slack
W. B. Kouwenhoven — W. R. Smith
L. Marinelli — L. S. Taylor

General Applications Group

General Applications Co-ordinating Committee

H. C. Coleman, *chairman*, Westinghouse Electric Corporation, East Pittsburgh, Pa.
C. C. Whipple — Elgin B. Robertson

Ex-officio
Chairmen of the five following technical committees in the general applications group

Air Transportation

S. D. Summers, *chairman*, Naval Research Laboratory, Washington 20, D. C.
J. W. Allen — T. J. Martin
G. W. Almassy — C. F. McCabe
J. H. Blankenbuehler — R. S. Mead
H. R. Brown — R. A. Millermaster
W. C. Bryant — J. D. Miner
J. P. Dallas — C. R. Moore
A. Fisher — W. F. Moore
D. E. Fritz — Joseph Nader
C. E. Gagnier — O. F. Olsen
S. H. Hanville, Jr. — W. E. Pakala
W. T. Harding — H. F. Rempt
V. P. Hessler — C. J. Rife
J. G. Hutton — R. A. Rugge
R. R. Jenner — K. R. Smythe
R. D. Jones — S. H. Webster
R. J. Lusk — J. A. White — W. W. West

AIR TRANSPORTATION SUBCOMMITTEES

1. Aircraft Electric Rotating Machinery Subcommittee

Scope: This subcommittee was organized in 1944 for the purpose of preparing standard test codes for aircraft electric rotating machinery. As a result, AIEE 800, Proposed Test Code for D-C Aircraft Machines, was published in March 1947 for one year trial use. The subcommittee now is preparing "Rating Standards or Engine-Driven Generators."

D. E. Fritz, *chairman* — R. D. Jones
J. W. Allen — L. R. Larson
A. Fisher — A. N. Lawrence
S. H. Hanville, Jr. — R. R. Smith — G. W. Sherman

2. Aircraft Systems Subcommittee

Scope: The purpose of this subcommittee is to formulate a report on the basic and accepted considerations involved in the application practice of aircraft electrical systems. This report shall contain information of the following character: an explanation of fundamental electrical problems, outlines of systematic procedures for analysis and computation of aircraft electrical system performance, and formulation of general application practices which will assure correct coordination of equipment.

W. F. Moore, *chairman* — G. A. Phillips
J. W. Allen — D. H. Scott
H. B. Bunce — K. R. Smythe
H. L. Hildebrandt — A. F. Trumbull — A. J. Snyder

3. Subcommittee on Basic Principles of Altitude Rating of Electric Apparatus

Scope: This subcommittee will prepare no test codes nor standards for specific apparatus; but rather, it will prepare a report indicating the basic principles of altitude rating of electric apparatus. Such a report will be useful in the preparation of test codes and standards and in the design and testing of aircraft equipment. The first phase of the project will be from sea level to 50,000 feet altitude.

W. E. Pakala, *chairman* — J. G. Hutton
J. W. Allen — Chester A. Maple
T. R. Brown — A. T. McClinton
S. H. Hanville, Jr. — R. A. Rugge

4. Subcommittee on Aircraft Electrical Control Protective Devices, and Cable

Scope: Formation of test codes and operating standards for aircraft electrical control, protective devices, and cable. The subcommittee is engaged presently in the preparation of a test code for aircraft circuit interrupting devices and a test code for aircraft d-c generator voltage regulators is being prepared by a working group of the subcommittee.

R. J. Lusk, *chairman* — H. S. Moore
B. O. Austin — W. F. Moore
E. E. Magee — J. Ottmar
A. T. McClinton — J. H. Taylor
R. A. Millermaster — W. W. West

Domestic and Commercial Applications

M. M. Brandon, *chairman*, Underwriters Laboratories, Inc., 161 Sixth Avenue, New York 13, N. Y.
S. W. Andrews — C. H. Leatham
D. K. Blake — F. W. Linder
A. C. Bredahl — B. H. Martin
W. B. Buchanan — L. W. McCullough
O. Kendall Buck — K. W. Miller
O. K. Coleman — A. L. Riche
T. H. David, Jr. — C. F. Scott
R. W. Fleming — H. P. Seelye
L. R. Gamble — G. S. Smith
R. R. Herrmann — G. C. Tenney
T. C. Johnson — V. G. Vaughan, Sr.
Wesley Weinerth

Land Transportation

J. G. Aydelott, *chairman*, General Electric Company, locomotive and car equipment divisions, 2901 East Lake Road, Erie, Pa.
L. S. Billau — J. G. Inglis
L. W. Birch — R. L. Kimball
H. R. Blomquist — S. B. Lent
W. A. Brecht — T. M. C. Martin
H. F. Brown — P. A. McGee
D. M. Burckett — E. B. Meissner
C. N. Chase — Ira S. Nippes
W. J. Clardy — A. G. Oehler
Andrew Costic — W. R. Simmons
H. E. Dralle — Dwight L. Smith
Llewellyn Evans — Jacob Stair, Jr.
J. C. Fox — M. C. Swanson
A. P. Frey — R. G. Thring
K. H. Gordon — J. P. Tretton
W. S. H. Hamilton — R. S. Warren
P. H. Hatch — R. A. Williamson
G. L. Hoard — H. P. Wright

LAND TRANSPORTATION SUBCOMMITTEES

1. Heavy Traction Electrification Data Subcommittee

Scope: To collect and tabulate data covering power supply, conversion and distribution systems, and motive power of electrified railroads in the United States and to present them in a way to show the extent of existing electrifications and trends as indicated by chronological developments. Since 1933, general information on railway electrification, both domestic and foreign, has not been available principally because of the discontinuance of the collection of these data by the National Electric Light Association and the disbanding of the heavy electric traction committee of the American Transit Association. In January 1947, this subcommittee was formed and the work is divided into five projects.

L. W. Birch, *chairman* — W. J. Clardy
H. F. Brown — A. G. Oehler — F. H. Craton

Projects:
(*1-1*). Catenary overhead systems
(*1-2*). Third rail systems
(*1-3*). Electric locomotives
(*1-4*). Substations
(*1-5*). Power supply

The personnel of the projects is as follows:
(*1-1*) and (*1-2*). L. W. Birch, *chairman*; H. F. Brown
(*1-3*), (*1-4*), and (*1-5*). A. G. Oehler; F. H. Craton; W. J. Clardy

2. Heavy Traction Papers and Plans Subcommittee

Scope: To secure papers and discussion for the various AIEE meetings, covering matters of current interest in the field relating to railroad electrification, Diesel-electric locomotives, and all other applications of electricity to railroad rolling stock such as lighting and air conditioning of passenger cars. This is accomplished by correspondence and personal contact with the leading manufacturers of equipment, and the engineering personnel of the major electrified railroads and consulting engineering firms engaged in such projects.

H. F. Brown, *chairman* — A. L. Brecht
R. L. Kimball

3. Light Traction Papers and Plans Subcommittee

Scope: To secure papers and discussion for the various AIEE meetings, covering matters of current interest in the field relating to local transit, that is, subway, streetcar, and trolley coach systems, and applications of electric propulsion equipment to internally powered local transit vehicles.

W. J. Clardy, *chairman* — Harold R. Blomquist
Dwight L. Smith

4. Subcommittee on Revision of AIEE Standard 16 (Electric Railway Control Apparatus) ASA C48 Subcommittee

Scope: To revise AIEE Standard 16 (Electric Railway Control Apparatus) for the purpose of recognizing new processes, correction of errors, and inclusions of certain new functions and devices. These Standards last were revised in 1933. The subcommittee reported at the Montreal meeting June 1947 and is expecting to present a final report soon.

F. H. Craton, *chairman* — W. S. H. Hamilton
W. J. Clardy — J. G. Inglis

Marine Transportation

O. A. Wilde, *chairman*, Sun Shipbuilding and Dry Dock Company, Chester, Pa.
E. C. Alger — J. E. Jones
W. B. Armstrong — C. Krommenhock
R. A. Beekman — Clarence Lynn
H. C. Coleman — V. W. Mayer
P. J. DuMont — S. N. Mead
R. W. Erickson — W. H. Reed
J. B. Feder — E. M. Rothen
A. R. Gatewood — L. B. Sinclair
L. M. Goldsmith — C. W. Souder
P. A. Guise — E. H. Stivender
H. F. Harvey, Jr. — G. O. Watson
W. E. Jacobsen — F. A. Wickel
W. N. Zippler

MARINE TRANSPORTATION SUBCOMMITTEES

1. Power Generation Subcommittee

C. Lynn, *chairman* — L. M. Goldsmith
W. B. Armstrong — W. E. Jacobsen
R. A. Beekman — E. H. Stivender
H. C. Coleman — O. A. Wilde

2. Power Application Subcommittee

L. M. Goldsmith, *chairman* — W. E. Jacobsen
W. B. Armstrong — J. E. Jones
H. C. Coleman — C. Lynn
R. W. Erickson — E. H. Stivender

3. Wires and Cables Subcommittee

W. N. Zippler, *chairman* — W. E. Jacobsen
P. J. Dumont — V. W. Mayer

(*Continued on page 1795*)

J. B. Feder — W. H. Reed
A. R. Gatewood — F. A. Wicke

4. Switchboards and Control Subcommittee

H. C. Coleman, *chairman* — J. E. Jones
R. A. Beekman — C. Krommenhock
P. J. Dumont — L. B. Sinclair
H. F. Harvey, Jr. — E. H. Stivender

5. Distribution Subcommittee

H. F. Harvey, Jr., *chairman* — L. M. Goldsmith
W. B. Armstrong — P. A. Guise
R. W. Erickson — V. W. Mayer
A. R. Gatewood — F. A. Wickel
W. N. Zippler

6. Fittings and Appliances Subcommittee

J. B. Feder, *chairman* — H. F. Harvey, Jr.
E. C. Alger — V. W. Mayer
P. J. Dumont — E. M. Rothen
R. W. Erickson — L. B. Sinclair
P. A. Guise — O. A. Wilde

7. Communications and Alarm Subcommittee

W. H. Reed, *chairman* — C. Krommenhock
E. C. Alger — S. N. Mead
J. B. Feder — E. M. Rothen
A. R. Gatewood — L. B. Sinclair
C. W. Souder

8. Navigation Equipment Subcommittee

S. N. Mead, *chairman* — C. Krommenhock
E. C. Alger — E. M. Rothen
P. A. Guise — G. Souder
F. A. Wickel

9. Publicity, Personnel and History Subcommittee

R. A. Beekman, *chairman* — H. F. Harvey, Jr.
W. H. Reed

10. Editing Subcommittee

W. N. Zippler, *chairman* — H. F. Harvey, Jr.
J. B. Feder — W. H. Reed

Production and Application of Light

Harris Reinhardt, *chairman*, Sylvania Electric Products Company, 500 Fifth Avenue, New York 18, N. Y.

J. F. Angier — J. A. McDermott
L. H. Brown — F. H. Murphy
M. J. Dring — R. L. Oetting
Frank Hansen — R. C. Putnam
C. P. Hayes — D. W. Rowten
S. G. Hibben — E. H. Salter
O. W. Holden — R. G. Slauer
E. A. Linsday — H. F. Wall
H. E. Mahan — E. S. West
C. C. Whipple

PRODUCTION AND APPLICATION OF LIGHT SUBCOMMITTEES

1. Ultraviolet Radiations Subcommittee

Scope: The initial scope will be to sponsor the preparation of a report on modern ultraviolet sources. The group also would serve as a clearing house for all information relating to its specific field, and, will help in planning convention papers and securing speakers on this subject.

Allen J. Dusault, *chairman*

2. Nomenclature of Electronic Lamps Subcommittee

Scope: This subcommittee was formed for the purpose of co-operating with the subcommittee on electronic standards of the committee on electronics in the preparation of a system of definitions of electronic devices used as light sources. In this connection, light sources is taken as including sources of infrared, visible, and ultraviolet radiations.

E. H. Salter, *chairman* — L. R. Keifter
E. W. Beggs — R. C. Putnam
T. G. Sargent

3. Infrared Radiations Subcommittee

E. A. Lindsay, *chairman* — M. J. Bevins — G. Parmallee

Joint Subcommittees

Joint Subcommittee on Application of Probability Methods to Capacity Problems (Joint with Power Generation and System Engineering Committees)

G. Calabrese, *chairman* — H. W. Phillips
W. R. Blakeley — C. A. Roberts
H. Duryea — H. B. Smith
R. G. Hooke — H. P. St. Clair
H. A. Lott — G. M. Tatum
W. J. Lyman — V. A. Thiemann
K. W. Miller — C. W. Watchorn

Joint Subcommittee on Carbon Brushes (Joint with Rotating Machinery and Air Transportation Committees)

V. P. Hessler, *chairman* — H. E. Kenelpp
W. H. Autry — E. A. Lapham
H. R. Brown — T. M. Linville
J. V. Dobson — D. Ramadanoff
H. M. Elsey — Orrin Rutledge
C. J. Herman — S. D. Summers
L. H. Hilderbrandt — Atten: A. L. Van Emdon (Navy Department)

Joint Subcommittee on Standard Frequency Bands and Designations

Scope: To consult with various interested groups and recommend designated bands which conform, as closely as possible, with the desires and needs of the majority. A logarithmic system of bands seems to be indicated to break up this enormous range from a small fraction of a cycle per second to 10^{18} cycles per second or higher into bands which can be designated readily.

Thomas Spooner, *chairman* (representative, electronic standards subcommittee)
C. T. Burke (representative, instruments and measurements committee)
G. B. Ransom (representative, communication committee)
F. B. Silsbee (representative, ASA sectional committee C88)
J. E. McCormack (representing ASA Electric Light and Power Group)

Joint Subcommittee on Nucleonic Instruments (Joint with Nucleonics and Instruments and Measurements Committees)

Scope: Treatment of all matters pertaining to the design, construction, and application of devices used for the detection and measurement of nucleonic radiations. The activity of the subcommittee in this field will include:

1. Sponsorship of papers of two general kinds, namely, survey papers of a broad educational nature and descriptive papers covering developments primarily of interest to the membership.

2. Sponsorship of conference sessions on similar subjects.

3. Co-operation with the various existing committees of the AIEE and other organizations, particularly with respect to standardization and definitions. (In this latter instance, it is believed this subcommittee's efforts initially will be by way of review and suggestion.)

G. W. Dunlap, *chairman* — J. A. Hutcheson
E. E. Goodale, *secretary* — P. S. Johnson
William E. Barbour, Jr. — J. B. H. Kuper
L. F. Curtiss — Frank D. Lewis
F. J. Gaffney — G. A. Morton
W. H. Hall — H. W. Newson
M. M. Hubbard — M. A. Schultz
H. G. Weiss

Joint Subcommittee on Electronic Instruments (Joint with Electronics and Instruments and Measurements)

J. G. Reid, Jr., *chairman* — G. B. Hoadley
Rudolf Feldt, *vice-chairman* — Eric Isbister
W. H. Tidd, *secretary* — G. N. Mahaffey
H. W. Berry — C. W. Martel
L. T. Bourland — H. R. Meahl
C. T. Burke — David Packard
C. C. Chambers — T. B. Perkins
W. R. Clark — J. J. Slattery
H. F. Dart — E. R. Thomas
H. C. Drake — J. T. Thwaites
G. V. Elgroth — V. Ulrich
D. B. Fisk — A. H. Waynick
W. A. Geohegan — A. J. Williams, Jr.
E. R. Haberland — W. P. Wills

Present Activities:

1. Continuing a program of survey, information collation, and liaison among instrument manufacturers, tube manufacturers, and other groups interested in improving the performance of electron tubes in instrument and industrial applications.

2. To solicit, review, and sponsor technical papers and reports on electronic instruments.

Proposed Future Activities:

1. In the field of electronic instrumentation, an investigation of desirable characteristics for special purpose electron tubes (photoelectric tubes, cathode ray tubes, and so forth).

2. Investigation of desirable characteristics for circuit components to be used in instruments in conjunction with electron tubes (sockets, potentiometers, and so forth).

3. Investigation of the need for definitions and standards pertaining to electronic instruments.

Joint Subcommittee on Telemetering (Joint with Substation and Instruments and Measurements Committee)

Scope: Telemetering is assigned primarily to the committee on instruments and measurements and handled by a joint subcommittee comprised of members of both the committees on substations and on instruments and measurements. Telemetering problems in connection with automatic stations will be assigned by the chairman of the committee on instruments and measurements to the substation committee. Telemetering problems of a more general nature will be assigned by him to members of both main committees and where the problem is simply measurements it will be assigned only to members of the committee on instruments and measurements.

Substation Appointees:

W. A. Derr — M. W. Keck (representative, carrier current committee)
W. L. Hiscox, *secretary*
George S. Lunge — J. H. Vivian
A. P. Peterson — C. E. Winegartner

Instruments and Measurements Appointees:

C. K. Duff, *chairman* — J. T. Logan
P. A. Borden — E. E. Lynch
M. A. Bostwick — W. E. Phillips
E. C. Brown — G. M. Thynell

Subsections

Name	Chairman	Secretary	Secretary's Address
Baton Rouge (New Orleans Section)	S. J. Helfman	F. B. Avery	Southern Bell Tel. & Tel. Co., 555 Florida St., Baton Rouge 8, La.
Billings (Montana Section)	John R. Walker	Frank M. Holly	545 Park Place, Billings, Mont.
Binghamton Area (Ithaca Section)	J. R. Stover	W. J. Rider	P.O. Box 1081, Binghamton, N. Y.
Boulder City (Los Angeles Section)	Albert E. Hamilton	William M. Doak	P.O. Box 398, Henderson, Nevada
Casper, Wyo. (Denver Section)	R. M. Sensintaffar	C. R. McLean	Mountain States Power Co., Casper, Wyo.
Central Texas (North Texas Section)	W. D. Nuckols	A. E. Vickery	710 North 11th Street, Waco, Tex.
Centre County (Pittsburgh Section)	R. E. Armington	W. B. Sheppard	Elec. Engg. Dept., Pennsylvania State College, State College, Pa.
Charleston (South Carolina Section)	George Dibble	E. B. Woodward	1007 Montague Ave., North Charleston, S. C.
Charlotte (North Carolina Section)	Ben Martin	M. F. Leftwich	Duke Power Co. 1969, Charlotte, N. C.
Columbia (South Carolina Section)	J. F. Rader, Jr.	S. A. Ferguson	2329 Terrace Way, Columbia 41, S. C.
Corpus Christi (South Texas Section)	M. H. Lovelady	M. D. Jester	3629 Austin St., Corpus Christi, Texas
Forth Worth (North Texas Section)	F. E. Woodruff	C. K. Beyette	2304 Loraine Court, Fort Worth 3, Texas
Fox River Valley (Milwaukee Section)	Jesse W. Pomazal	Joseph J. Rock	Giddings & Lewis, Fond du Lac, Wis.
Freeport (Houston Section)	B. J. Nankervis	H. K. Brown	1414 West 5th St., Freeport, Texas
Fresno (San Francisco Section)	F. E. Miller	Clyde L. Smith	Pacific Gas & Electric Co., 1401 Fulton St., Fresno 24, Calif.
Great Falls (Montana Section)	Sidney E. McArthur	D. A. Johnson	Box 1689, Great Falls, Mont.
Hamilton (Toronto Section)	C. E. Moorhouse	E. S. Webb	Canadian Westinghouse Co., Hamilton, Ont., Canada
Hampton Roads (Virginia Section)	L. Saunders	K. O. Joyner	45 Algonquin, Hampton, Va.
Hudson Valley (New York Section)	M. S. Kozik	E. W. Paquin	Central Hudson Gas & Elec. Corp., Poughkeepsie, N. Y.
Jackson (Miss.) (New Orleans Section)	Joseph B. Fountain	A. N. Saxon	Graybar Elec. Co., 758 Ricks St., Jackson, Miss.
Jacksonville (Florida Section)	R. M. Garth		
Johnstown (Pittsburgh Section)	A. M. Baker	W. M. Rohrer	Johnstown Center, University of Pittsburgh, Johnstown, Pa.
Lake Charles (New Orleans)	J. W. Kirkland	W. W. Crossley	1317 Shaw St., Lake Charles, La.
Lancaster–York (Maryland Section)	J. L. Stauffer	W. H. Freund	RCA Mfg. Co., Lancaster, Pa.
Lima (Dayton Section)	L. C. Schaefer	O. M. Swain	Westinghouse Electric Corp., Lima, Ohio
Miami (Florida Section)	Harvey F. Pierce	C. V. Booth	c/o M. H. Connell & Associates, Langford Bldg., Miami 32, Fla.
Mid-State (North Carolina Section)	F. R. Jackson, Jr.	L. H. Allcorn, Jr.	2425 Elizabeth Ave., Winston-Salem 7, N. C.
New Hampshire (Boston Section)	L. H. Faulkingham	H. K. Coates	273 Main St., Nashua, N. H.
New Jersey (New York Section)	Lawrence J. Lunas	J. L. Blackburn	Westinghouse Electric Corp., Newark 1, N. J.
Oak Ridge (East Tennessee Section)		M. P. Falls	105 Vermont Ave., Oak Ridge, Tenn.
Ottawa (Montreal Section)	G. R. Davis	R. M. Morris	National Research Council, Sussex St., Ottawa, Ont., Canada
Quad Cities (Iowa Section)	Raymond C. Judd	E. H. Breckenfelder	P.O. Box 537, Muscatine, Iowa
Red River Valley (Minnesota Section)	Thomas C. Wright	G. O. Gerth	Otter Tail Power Co., Fergus Falls, Minn.
Richmond (Virginia)	Bruce G. Halsted	C. E. McMurdo	3523 Patrick Ave., Richmond 22, Va.
Sacramento (San Francisco Section)	E. S. Prud'Homme	Charles R. Day	Sacramento Municipal Utility Dist., P.O. Box 2391, Sacramento, Calif.
St. Maurice Valley (Montreal Section)	J. J. Dupuis	Donald King	P.O. Box 70, Shawinigan Falls, Que., Canada
Saginaw Valley (Michigan Section)	H. R. Walker	E. L. Holmgren	400 Park Ave., Bay City, Mich.
Sangamon (Illinois Valley Section)	W. W. Sherwood	J. F. Kurzska	Central Illinois Public Service Co., Illinois Bldg., Springfield, Ill.
San Jose (San Francisco Section)	J. Scott Kay	L. O. Templeton	Westinghouse Electric Corp., Project 28, Sunnyvale, Calif.
Shasta (San Francisco Section)	M. E. Guile	W. G. Whitney	Pacific Gas & Electric Co., 301 Main St., Chico, Calif.
Tampa (Florida Section)	R. S. Davis		
Tri-State (West Virginia Section)	H. F. Rosier	G. D. Wilhoit	1029 Seventh Ave., Huntington, W. Va.
West Central Texas (North Texas Section)	E. N. Mitchell	H. L. Pearce, Jr.	1634 S. 7th St., Abilene, Texas
Western Virginia (Virginia Section)	G. L. Seay	J. B. Whitmore	P.O. Box 2021, Roanoke, Va.
Wilmington (Philadelphia Section)	Henry Evans	William J. Mearns	Hercules Powder Co., 900 Market St., Wilmington 99, Del.
Zanesville (Columbus Section)	R. P. Thompson	R. W. Hartsook	1637 Norwood Blvd., Zanesville, Ohio

Geographical District Executive Committees

District	Chairman (Vice-President, AIEE)	Secretary (District Secretary)	Chairman, District Committee on Student Activities
1 North Eastern	Victor Siegfried, American Steel & Wire Co., Worcester 7, Mass.	Frederick G. Webber, 9 Federal Court, Springfield 5, Mass.	E. R. McKee, University of Vermont, Burlington, Vt.
2 Middle Eastern	G. W. Bower, 127 Hopkins Ave., Haddonfield, N. J.	A. C. Muir, Berwind-White Coal Mining Co., 1138 Comm. Trust Bldg., Philadelphia 2, Pa.	Kenneth F. Sibila, University of Akron, Akron 4, Ohio
3 New York City	J. L. Callahan, R. C. A. Laboratories, Radio Corporation of America, 66 Broad St., New York 4, N. Y.	W. J. Barrett, New Jersey Bell Telephone Co., 540 Broad St., Newark 1, N. J.	F. A. Wahlers, Polytechnic Inst. of Brooklyn, 99 Livingston St., Brooklyn 2, N. Y.
4 Southern	J. H. Berry, Electric Dept., Virginia Electric and Power Co., Norfolk 1, Va.	T. H. Mawson, Commonwealth & Southern Corp., 600 N. 18th St., Birmingham 2, Ala.	L. V. McLean, Louisiana State University, Baton Rouge 3, La.
5 Great Lakes	E. W. Seeger, Cutler-Hammer, Inc., 315 North 12th St., Milwaukee 1, Wis.	N. C. Pearcy, Pioneer Service & Engineering Co., 231 South La Salle St., Chicago 4, Ill.	W. H. Gamble, South Dakota State College, Brookings, S. D.
6 North Central	I. M. Eliestad, Northwestern Bell Telephone Co., 823 Telephone Bldg., Omaha 2, Nebr.	M. L. Burgess, Westinghouse Electric Corp., 117 N. 13th St., Omaha 2, Nebr.	J. O. Kammerman, South Dakota School of Mines & Tech., Rapid City, S. D.
7 South West	G. N. Pingree, General Electric Co., 1801 North Lamar St., Dallas 2, Texas	Gibbs A. Dyer, Southwestern Bell Tel. Co., Dallas 1, Texas	F. W. Tatum, Southern Methodist University, Dallas 5, Texas
8 Pacific	D. I. Cone, Pacific Tel. & Tel. Co., 140 New Montgomery St., San Francisco 5, Calif.	B. D. Dexter, 245 Market St., San Francisco 6, Calif.	I. J. Sandorf, Univ. of Nevada, Reno, Nev.
9 North West	Richard McKay, Washington Water Power Co., West 825 Trent Ave., Spokane 6, Wash.	H. C. Glaze, Jr., General Electric Co., S. 162 Post St., Spokane 8, Wash.	Vinson L. Palmer, University of Washington, Seattle 5, Wash.
10 Canada	D. G. Geiger, Bell Telephone Co. of Canada Ltd., 76 Adelaide St. W., Toronto 1, Ont.	J. Taylor Fisher, 76 Adelaide St. West, Toronto 1, Ont.	W. B. Coulthard, University of British Columbia, Vancouver, B. C.

NOTE: Each District executive committee includes also the chairmen and secretaries of all Sections within the District, a member of the Sections Committee resident in the District, and the District vice-chairman of the AIEE membership committee.
